Isolation of the etiological agents. The etiology of swine influenza has been elucidated by Shope in a comprehensive series of investigations (Shope, 1931 *a*, *b*, 1932, 1934 *a*, *b*, 1935, 1936 *b*, *c*, 1937 *a*, *b*, *c*, 1938, Lewis and Shope, 1931; Orcutt and Shope, 1935). Shope has shown that the disease can be transmitted readily by contact between infected and healthy pigs or more directly by instillation of infective material intranasally The infective element consists of the virus of swine influenza and *Hemophilus influenzae suis;* the former is the most important and can produce a mild catarrhal condition *per se*

Hemophilus influenzae suis This gram-negative hemophilic organism is constantly present in association with the virus, by itself it has only a feeble pathogenicity for pigs Swine strains are antigenically heterogeneous. Known human strains of *H. influenzae* (meningeal or respiratory) show no synergistic effect on swine virus (Mote and Fothergill, 1940)

Swine influenza virus. By itself this produces in pigs a mild attack of swine fever (filtrate disease), but with the bacterium the experimental disease is severe and resembles the natural condition The virus is pneumotropic and can be isolated from the turbinates, tracheal exudate, and lungs of infected pigs, it does not occur in the blood or viscera (Orcutt and Shope, 1935). The virus is pathogenic for the ferret, and pneumonia develops when inoculated under ether

The virus is also pathogenic to mice, and may be isolated directly from cases of swine influenza by inoculation in these animals without preliminary ferret passage. Pneumonia usually follows nasal instillation of virus Strains vary somewhat in the ease with which they become adapted to mice (Shope, 1935)

When *H suis* and swine virus are inoculated together on the chorio-allantois, a higher proportion of embryos is killed than by either component separately This enhancing effect is produced equally well by old laboratory cultures, heat-killed organisms, or filtered extracts of frozen and dried organisms (Bang, 1943, *a*, *b*)

It is thus seen that the properties of the virus of swine influenza closely resemble those of human influenza The question of the antigenic relationship of the two viruses is discussed elsewhere (see p 587), where it will be seen that it is very close

Passage The disease can be maintained under experimental conditions by subjecting fresh animals to contact infection with a declared case, both the bacterium and virus are transferred, and eventually a typical attack of swine influenza develops Shope (1934 *a*) records an experiment where he had been passing a strain of swine influenza in this way when it suddenly became less contagious, it was found that only the virus was now being transferred, the disease being the mild form due to this agent alone (filtrate disease)

Survival of virus in nature Shope (1941 *a*) found that multiple intramuscular injections of *H suis* precipitated the double infection in apparently normal swine, suggesting that the animals were harboring the virus in a latent condition He found (1941 *b*) that the swine lung worm acts as an intermediate host, carrying the virus in a "masked" noninfective form To produce infection, a stimulant, such as injections of *H suis,* is needed Infection cannot be provoked in the summer months The virus can persist in the lung worm for at least 2 years. Swine carrying infected lung worms develop pneumonic

consolidation most markedly around the worms In certain cases, after provocative injections, infested swine become immune, but not all; in these cases the worms are probably not situated in the respiratory tract Later (1943 *a*) he reported finding virus in lung worm ova obtained from the respiratory tract or feces of infected or convalescent swine. Masked virus persists for over one year in lung worm larvae in the earthworm *Allolobophora caliginosa f typica* (Savigny) and *f. trapezoides* (Dugès). Shope (1943 *b*) found masked virus in lung worm larvae from earthworms dug up in the Middle West. There is no doubt from these researches that the swine lung worm is the reservoir of swine influenza virus infection, and the intermediate host in the field.

[illegible] recovery from infection, "filtrate disease" (i e, the [illegible] both the virus and the [illegible] ne influenza, animals are [illegible] sistance to infection after vaccination, injections of the bacterium alone confer only a partial immunity capable of modifying, but not preventing, the course of a subsequent attack of swine influenza (Shope, 1937 *b*). Injections of tissue containing virus are effective, and swine fever can be prevented by inoculation of infected ferret lung given intramuscularly or subcutaneously. (For a paper on the development of immune bodies in infected swine, see Rosenbusch and Shope, 1939)

Ferrets can be immunized by subcutaneous injections of infective homologous lung, mouse or pig lungs do not, however, achieve this result (Shope, 1936 *b*). Mice also can be immunized subcutaneously by injection of homologous lung, ferret or pig lung is not effective (Shope, 1936 *b*). However, if the intraperitoneal route is used for immunization, then ferrets and mice can be immunized by virus-infected tissue from any of these 3 animals

Equine influenza Although this disease is caused by a hemolytic streptococcus and filtrable virus, there is no evidence that the virus is related to human or swine strains of influenza (Jones and Maurer, 1942, 1943).

Calf influenza An influenzal pneumonia with enteritis occurs in calves. The etiology is uncertain, but it appears to be due to a filtrable virus, probably together with a hemophilic organism (Gilmore, 1939, Lamont and Kerr, 1939, Baker, 1943).

CLINICAL FEATURES OF HUMAN INFLUENZA

The signs and symptoms of influenza proved by laboratory tests to be due to virus A or B are usually fairly characteristic, although infections can range in severity from those that are only subclinical to fatal pneumonias.

It is useful to use the term "clinical influenza" for cases occurring in a proved epidemic and diagnosed on clinical grounds alone (Horsfall *et al*, 1940). In any influenza epidemic, only a proportion of cases of clinical influenza will show laboratory evidence of infection. The term influenza Y is given to cases clinically typical, but apparently due to infection with an unknown agent.

There is the additional difficulty that there are a number of other infections of the respiratory tract, not unlike influenza clinically, but of unknown etiology The term "febrile catarrh" has been used for these cases (Stuart-Harris, 1937 *a*, *et al*, 1938, Wauchope, 1935), but it is not really possible to achieve a differentiation from influenza on purely clinical grounds (Stuart-Harris, 1945 *a*). These catarrhs are probably caused by Pfeiffer's bacilli, streptococci, and pneumococci (Thomson and Thomson, 1935), and sometimes by the virus of the common cold (Stuart-Harris, 1945 *a*), or the viruses of atypical pneumonia American workers have drawn attention to a condition they call "catarrhal fever" (*U.S Nav. Lab. Res Unit*, 1944 *c*) The differential points from influenza are the insidious onset of catarrhal fever, the predominance of respiratory as opposed to constitutional symptoms, the productive and paroxysmal cough, and the frequency of pharyngitis and tonsillitis with exudate (see also Stuart-Harris *et al*, 1938).

Unless complete laboratory tests are carried out, cases will be labelled as influenza that are not Further, Ziegler *et al* (1947) have shown that double infection with atypical pneumonia and influenza may occur.

It should not be necessary to give a detailed description of the features of the common type of infection due to virus A, but it is useful to have some indication as to what constitutes "typical influenza" Stuart-Harris (1945 *a*) gives the following description of a typical case in an adult:

On the first day the patient has a headache, feels shivery and ill. He sleeps poorly and wakes at intervals with a dry cough. Aching in the back and limbs is common, and so are dizziness, vomiting, and fainting. The temperature rises to 102° F., and there is a frontal headache, anorexia, and drowsiness. The face is flushed and the lips cyanosed. On the following day the temperature falls, but the cough persists. On the 3rd day there is renewal of fever, and the cough continues The fever usually subsides after 3–5 days. Stuart-Harris refers to atypical attacks, in which there may be a premonitory cold, vomiting, acute coryza, a sore throat, or aphonia. Some cases are afebrile, while others show a diphasic fever. Pharyngitis was found to be a characteristic feature in an outbreak of A infection, and pharyngeal swabs showed destruction of epithelium, and mononuclear exudate (Adams, Pennoyer, and Whiting, 1946).

There are probably no significant differences between influenza A and B, but the onset of the latter may be more insidious, the illness, milder, and the symptoms less uniform, the infection can vary in severity from a coryza to a severe attack, and nausea and vomiting may be relatively frequent (Taylor *et al*, 1942–3, Hare, Stamatis, and Jackson, 1943, Beveridge and Williams, 1944, Stuart-Harris, 1945 *a*, Jackson, 1946, Hirst *et al*, 1947). Premonitory symptoms of coryza have been noted in some outbreaks, but have been absent in others.

Comparison with Pandemic Influenza

Epidemic influenza is very much less severe than pandemic, the attack rate and death rate being much lower. With regard to clinical features, the uncomplicated cases are remarkably alike At the present day, fortunately, there is much less tendency for respiratory complications to develop An interesting report is that of Doull and Bahlke (1933), who had the opportunity of observing nurses in the 1918–19 and the 1928–9 outbreaks In 1928–9 pneumonia was rare and the disease seldom proved fatal. Both outbreaks were characterized by leukopenia, muscular pains, and pyrexia, but these were distinctly less prominent in 1928–9

Influenzal Encephalitis

Greenfield (1930, and see *Report*, 1930) drew attention to the occurrence of 3 cases of acute disseminated encephalomyelitis following attacks of influenza. Clinically the picture was of a severe paraplegia with incontinence of urine and feces. Histologically there was found perivascular demyelination and cellular infiltration, exactly as in similar cases following on measles and vaccination This question is further discussed in the section on postvaccinal encephalitis (see Ch. XXXV).

Leigh (1946) in London observed a small series of cases of encephalitis, myelitis, and polyneuritis, occurring at the peak of the 1946 influenza B outbreak Although it was not possible to be certain, it appeared likely that most of the cases suffered from influenza a few days before the onset

Broun *et al* (1945) isolated an influenzal type of virus from the CSF of a case of encephalitis developing 6 weeks after a respiratory illness resembling mild influenza

Woodside Throat

There is some suggestion that an acute throat infection seen in Australia may be due to influenza virus (Mawson, 1942).

DISTRIBUTION OF VIRUS IN THE BODY

Virus is most easily recovered from nasopharyngeal washings, or gargling, nasal secretion may also prove infective. Virus is usually present for the first few days

of the illness only, but in 1 case it was found as late as the 7th day (Francis *et al*, 1937 *a*) Virus has also been recovered from the throat of healthy contacts, and in 1 case 24 hours before the onset of influenza (Francis *et al*, 1937 *a*, Crowley, Thigpen, and Rickard, 1944).

BACTERIOLOGY OF UNCOMPLICATED INFLUENZA

Hoyle and Fairbrother (1937 *a*) failed to find pathogenic organisms in specimens yielding influenza virus, but pneumococci and *H. influenzae* may occur (Stuart-Harris *et al*, 1938). In general, pathogenic bacteria are found more readily in cases complicated by pneumonia (see below).

Cases of influenza nursed in general wards are liable to cross infection, and Cruickshank and Muir (1940) have described a series of cases of secondary infection of the upper respiratory tract due to hemolytic streptococci.

RESPIRATORY COMPLICATIONS OF INFLUENZA

It is now generally believed that the virus of influenza (A or B) is itself responsible for the ordinary uncomplicated case of epidemic influenza The virus depresses the resistance of the respiratory tissues and opens the way for secondary invasion by organisms from the throat Recent reports have shown that staphylococci and streptococci may be isolated from the lung, as they were in 1918–19 Although the virus itself produces lesions in the respiratory tract of man, as it does in animals, it appears that fatality is largely determined by secondary infection and the development of pneumonia Pneumonia usually comes on within 14 days of the onset of influenzal symptoms

Scadding (1937) has formulated the following views, based on his correlation between the clinical and pathological features of cases (influenza A) occurring in 1936–7. He regards the influenza virus itself as capable of causing a descending infection of the respiratory tract, which may progress to any level In the more severe cases, however, the process is modified because of secondary bacterial invasion. He regards the fulminant cases as due to the combined action of the virus plus a virulent bacterium The virus acts by lowering the resistance of the tissues to invasion by Pfeiffer's bacillus, streptococci, staphylococci, or pneumococci, and it is due to these organisms that fatalities occur

As Scadding points out, there is an analogous condition in poison-gas pneumonia where the [illegible]

severe attack

Distribution of Virus and Bacteria in Respiratory Complications

In certain cases influenza virus can cause a fatal pneumonia, and there have been reports of the isolation of influenza virus A by itself from the lungs of such cases (Finland *et al*, 1945; Parker *et al*, 1946). McIntosh and Selbie (1937 *a*, *b*) isolated an influenzal type of virus from the lungs of 2 fatal cases, the virus had somewhat unusual properties

According to Stuart-Harris (1945 *a*), pneumococci, either in pure culture or associated with other organisms, are the commonest bacteria occurring in pneumonia following influenza A (see also Scadding, 1937, Stuart-Harris *et al*, 1938, Nigg *et al*, 1942) Jackson (1946) described a series of cases of pneumococcal pneumonia in an epidemic of influenza B

Hemolytic streptococci are unusual secondary invaders, but have been reported as occurring in pure culture or associated with other organisms (Watjen, 1937, Davis, 1944)

Nonhemolytic streptococci have been reported (Emdin, 1942)

Staphylococcus aureus is the most serious secondary invader, and there has

been a number of reports of its isolation from the bronchi or lungs of fatal cases of influenzal pneumonia. Thus this organism has been isolated from the lungs of cases of pneumonia occurring during influenza epidemics (Burgess and Gormly, 1930; Scadding, 1937; Finland *et al.*, 1942; Michael, 1942; Wollenman and Finland, 1943).

More definite evidence of the association of *Staph. aureus* and influenza virus has been obtained by workers who have isolated virus A and the organism from the bronchi or lungs at the same time (Stuart-Harris *et al*, 1938, Stokes and Wolman, 1940, Parker *et al.*, 1946). Influenza virus B and *Staph. aureus* have also been recovered from the bronchi or lungs in influenzal pneumonia (Himmelweit, 1943; Burnet, Stone, and Anderson, 1946).

Staph. aureus is more usually present in pure culture, but may be associated with pneumococci, *H. influenzae*, or hemolytic streptococci (Wollenman and Finland, 1943; Davis, 1944; Parker *et al.*, 1946).

PATHOLOGY

In general, the changes in epidemic influenza are similar to those in pandemic influenza, described fully above.

Virus pneumonia. There is no doubt that in certain cases influenza virus itself produces a fatal pneumonia, without the presence of secondary invaders The virus can give rise to a range of pathological lesions from tracheitis and pharyngitis, to bronchitis, bronchiolitis, and bronchopneumonia. The pathological features of the lesions due to the virus alone have been described by various authors (McCordock and Muckenfuss, 1933; Scadding, 1937, Parker *et al*, 1946).

Thus, McCordock and Muckenfuss found that the interstitial bronchopneumonia of influenza closely resembles "virus pneumonia" that can be produced in animals with vaccinia. The earliest influenzal lesion in the lungs is a hemorrhagic and edematous lobular [illegible] lar and alveolar ep[illegible] Later, an interstiti[illegible]e and a nonpurulent exudate in the alveoli Gray carried out the pathological examination of Scadding's cases (*vide supra*). He found an interstitial inflammation and some necrosis of the alveolar walls with resultant hemorrhage. Necrosis of the tracheal and bronchial epithelium was also prominent.

In the past a necrotizing bronchiolitis has been regarded as characteristic of influenzal pneumonia in man. Parker *et al.* did not, however, find this change in cases apparently due to the virus alone. They suggest that this particular lesion is due to invasion by staphylococci (see below). They found edema, alveolar hemorrhages, fibrin exudate, and formation of a hyaline membrane The bronchiolar epithelium was intact, but the walls were infiltrated with leukocytes, the lumina contained mucus, leukocytes, red cells, and fibrin

Pneumococcal pneumonia Influenzal pneumonia associated with the presence of pneumococci usually has the pathological features of lobar pneumonia It is possible that a number of small localized "epidemics" of pneumococcal pneumonia may, in reality, be secondary to influenzal infection For example, a Type I outbreak was subsequently shown by serological tests to be associated with infection due to virus B (Commission, 1945).

Streptococcal pneumonia Watjen (1937) examined cases of influenzal pneumonia associated with the presence of hemolytic streptococci He found a widespread hemorrhagic and inflammatory involvement of the respiratory passages and lung tissue similar to that seen in 1919

Staphylococcal pneumonia At the present day, the majority of fatal cases of influenzal pneumonia seems to be associated with *Staph aureus* The pathological features of acute infection with *Staph aureus* and virus A have been described (Stokes and Wolman, 1940, Wollenman and Finland, 1943, Parker *et al*, 1946)

Finland *et al* (1942) who observed 66 cases suggested that under certain conditions the organism assumed an epidemic spread together with the virus They found that staphylococcal infections varied from a simple tracheobronchitis to a fulminating acute and fatal hemorrhagic pneumonia.

The lungs usually show a bilateral involvement most marked in the posterior and dependent portions. Multiple abscesses related to the bronchi and bronchioles are common.

The trachea, bronchi, and bronchioles have lost most of their epithelial lining in a necrotizing process, and their walls are infiltrated with inflammatory cells and much fibrin. A hyaline membrane may be found. The alveolar capillaries are congested and the alveoli edematous, and contain red cells and polymorphs Sometimes the picture is more of an acute hemorrhage than an infection.

Chronic lesions may also occur in infections with virus A and *Staph aureus* (Wollenman and Finland, 1943). There are large bronchiectatic cavities with firm fibrous walls There is some regeneration of the bronchial mucosa. The alveolar lining may be replaced by a low cuboidal epithelium Alveolar exudate shows evidence of organization

The pathological features of acute infection with *Staph aureus* and virus B resemble those described for virus A. Thus Himmelweit (1943) reports a case in which the lungs showed blood-stained edema, with patchy peribronchial consolidation. The epithelial lining of the trachea and bronchi was shed, and the lungs showed a patchy bronchopneumonia.

It has been suggested that in addition to respiratory complications, virus A may cause myocarditis (Finland *et al*, 1945).

MORTALITY

It will be recalled that during t[illegible] deaths occurred in young adults Under [illegible] influenza mortality statistics since 190[illegible] disappear, but that it took about 10 [illegible] was again present, that is to say, before the maximum number of deaths again occurred in those over 60 years of age. The majority of epidemics occurs in December and January, and Spear (1934) has shown that the week of maximum deaths (in London) is from the 8th to the 10th week of the year, i e, in March) In a large country the total mortality from epidemic influenza remains considerable, thus, in the United States of America, Collins (1930) reported that in the 1928–9 epidemic about 50,000 deaths occurred from influenza and pneumonia (in excess of expected seasonal rate) In the 1920 epidemic 100,000 deaths occurred, while in the epidemics of 1922, 1923, 1926, and spring 1928 there were 150,000 deaths. (For a detailed study of the influenza and pneumonia mortality from 1910 to 1944 in America, see Collins *et al*, 1930, Gover, 1943, Collins, 1944, 1945.)

Mortality from influenzal pneumonia is still very high, thus Collins (1934), studying the American 1928–9 epidemic, found that the fatality rate of pneumonic cases varied from 10 per cent to 33 per cent

Epidemic influenza has a noticeable effect in increasing the mortality from other respiratory diseases in which it is not actually mentioned as a contributory cause of death Thus Stocks (1935), studying the statistics from 1921 to 1933, found that whooping cough had the highest rise. Not only respiratory diseases, but also diseases of the heart and nervous system, showed an increased mortality due to influenza epidemics

EPIDEMIOLOGY

The term "epidemic influenza" should be restricted in epidemiological discussions to widespread prevalences producing a definite excess mortality from influenza and pneumonia in large populations, the term "outbreak of influenza"

been a number of reports of its isolation from the bronchi or lungs of fatal cases of influenzal pneumonia. Thus this organism has been isolated from the lungs of cases of pneumonia occurring during influenza epidemics (Burgess and Gormly, 1930, Scadding, 1937, Finland *et al.*, 1942; Michael, 1942; Wollenman and Finland, 1943).

More definite evidence of the association of *Staph. aureus* and influenza virus has been obtained by workers who have isolated virus A and the organism from the bronchi or lungs at the same time (Stuart-Harris *et al.*, 1938, Stokes and Wolman, 1940; Parker *et al*, 1946). Influenza virus B and *Staph. aureus* have also been recovered from the bronchi or lungs in influenzal pneumonia (Himmelweit, 1943, Burnet, Stone, and Anderson, 1946).

Staph. aureus is more usually present in pure culture, but may be associated with pneumococci, *H. influenzae*, or hemolytic streptococci (Wollenman and Finland, 1943; Davis, 1944, Parker *et al.*, 1946).

PATHOLOGY

In general, the changes in epidemic influenza are similar to those in pandemic influenza, described fully above.

Virus pneumonia. There is no doubt that in certain cases influenza virus itself produces a fatal pneumonia, without the presence of secondary invaders. The virus can give rise to a range of pathological lesions from tracheitis and pharyngitis, to bronchitis, bronchiolitis, and bronchopneumonia. The pathological features of the lesions due to the virus alone have been described by various authors (McCordock and Muckenfuss, 1933, Scadding, 1937, Parker *et al*, 1946)

Thus, McCordock and Muckenfuss found that the interstitial bronchopneumonia of influenza closely resembles "virus pneumonia" that can be produced in animals with vaccinia The earliest influenzal lesion in the lungs is a hemorrhagic and edematous lobular consolidation Microscopically there is necrosis of the bronchiolar and alveolar epithelium and walls, with coagulum and red cells in the alveoli Later, an interstitial pneumonia follows with infiltration of the interstitial tissue and a nonpurulent exudate in the alveoli. Gray carried out the pathological examination of Scadding's cases (*vide supra*) He found an interstitial inflammation and some necrosis of the alveolar walls with resultant hemorrhage. Necrosis of the tracheal and bronchial epithelium was also prominent

In the past a necrotizing bronchiolitis has been regarded as characteristic of influenzal pneumonia in man Parker *et al* did not, however, find this change in cases apparently due to the virus alone. They suggest that this particular lesion is due to invasion by staphylococci (see below). They found edema, alveolar hemorrhages, fibrin exudate, and formation of a hyaline membrane The bronchiolar epithelium was intact, but the walls were infiltrated with leukocytes, the lumina contained mucus, leukocytes, red cells, and fibrin

Pneumococcal pneumonia Influenzal pneumonia associated with the presence of pneumococci usually has the pathological features of lobar pneumonia It is possible that a number of small localized "epidemics" of pneumococcal pneumonia may, in reality, be secondary to influenzal infection For example, a Type I outbreak was subsequently shown by serological tests to be associated with infection due to virus B (Commission, 1945).

Streptococcal pneumonia. Watjen (1937) examined cases of influenzal pneumonia associated with the presence of hemolytic streptococci He found a widespread hemorrhagic and inflammatory involvement of the respiratory passages and lung tissue similar to that seen in 1919

Staphylococcal pneumonia At the present day, the majority of fatal cases of influenzal pneumonia seems to be associated with *Staph aureus* The pathological features of acute infection with *Staph aureus* and virus A have been described (Stokes and Wolman, 1940, Wollenman and Finland, 1943, Parker *et al*, 1946)

The recent history of influenza in those countries where it has been most studied is as follows, information about these countries as well as others being given also in the tables.

British Isles In 1933 and 1937 there were many epidemics apparently due to virus A, which was readily isolated by ferret inoculation. Influenza was prevalent in 1934, 1936, 1938, 1940, and 1942, but there was little evidence of the presence of virus A This virus was isolated in 1935, 1939, and 1941, but was not easy to establish in ferrets or mice (Andrewes, 1942 *c*). In 1943 there were at first sporadic cases, then outbreaks, and then a widespread epidemic of A infection, the virus being readily demonstrated by ferret inoculation. Influenza A was not found in 1944 or 1945.

Infections due to virus B occurred in 1939, 1943, and 1946. Britain and N. America usually suffer from influenza epidemics at more or less the same time.

N. America. No less than 16 widespread epidemics of influenza occurred in the U. S A. between 1920 and 1944 These epidemics have been accounted for on the basis of infection with influenza A occurring every 2–3 years, and influenza B every 4–6 years (Commission, 1946 *a*). Thus these authors suggest that A infections occurred in 1923, 1926, 1929, 1931, 1933, 1935, 1937, 1939, 1941, and 1943, B infections probably occurred in 1922, 1928, 1932, 1936, 1940, 1945, and 1946. The B outbreaks of 1936 and 1940 were similar epidemiologically to A infections. Since 1940, B infection has been sporadic, but at the end of 1945 there were again outbreaks.

Australia Melbourne experienced major waves of A infection in 1935, 1939, and 1942. Sporadic cases were recognized in 1943 and 1945.

should be restricted to localized concentrations which do not cause an appreciable effect on the mortality of large populations (Commission, 1946 *a*).

Geographical Distribution

The last pandemic ended in 1919, and during the next 10 years major influenza epidemics occurred in 1920, 1922, 1926–7, 1928–9 and 1930–1, in many parts of the world. Information on world distribution of influenza has been furnished by the *League of Nations Epidemiological Reports* (1931, 1933, 1935) and various other sources (Collins, 1930, 1944, 1945; Collins and Gover, 1932–3, 1935, Doull and Bahlke, 1933; Huber, 1933; Rösler, 1933; Ganz, 1934, Reiter, 1934, Shepard, 1934; Underwood, 1934; Eckardt *et al.*, 1936, Gover, 1936, Syssine, 1936, Danson, 1937, Dennig, 1937, *Brit. med. develop antibody response. There is no reason, however, why such cases should not yield virus from washings.

Incidence of Attack

A usual attack rate in the more severe epidemics has been between 10 and 20 per cent. of the populace. Thus, Huber (1933) studied 5 epidemics in soldiers in New York, occurring in 1922, 1926, 1928, March 1932, and December 1932. He found that in the 1st epidemic 9 5 per cent of the population was affected, but 20 per cent. in the 5th. Underwood (1934), studying over 17,000 persons in Leeds (England), found an attack rate of approximately 16 per cent. In the 1936–7 epidemic in London, Blood (1937) reported an attack rate of 19 1 per cent. in factory workers.

in children under 10. There has been no true peak in the young adult group, such as characterized pandemic influenza, since 1922 (see Collins, 1945)

Method of Spread

The main sources of infection are cases of the disease. Cases are probably infective in the late incubation period as well as during the first few days of illness. There is evidence that subclinical infection can occur naturally; such persons show no symptoms of infection, but develop an increase in virus neutralizing antibodies These people presumably can disseminate virus to other more susceptible persons

Influenza is essentially a droplet-spread aerial infection, and mice and human beings can be infected experimentally by inhalation. Virus can persist in air for some hours, and it has been shown experimentally that it persists for a much longer time in a dry atmosphere than a moist one (Loosli *et al*, 1943, and see Ch. LX). Fomites may play a part in transmitting infection. Virus can probably survive long enough on drinking and eating utensils to infect other persons, if the "washing-up" process is inadequate, mucoid material seems to preserve infectivity (see p 625). Virus can also survive in dust, fabrics, and materials (see p 625).

Hare and Mackenzie (1946) on the basis of experiments with *B. prodigiosus* suggest that important sources of infection are clothing and objects in the vicinity of the patient. The majority of exhaled particles falls downward onto the clothing and may be shaken off later, to be dispersed in the atmosphere, giving rise to infection in other persons These authors agree that infection may occur more directly by forcible expulsion of droplets as in sneezing, but suggest that indirect infection by dispersal of dried secretions is more likely It has been shown experimentally that sweeping the floor of a room in which virus has been atomized increases the infectivity of the atmosphere for mice (Loosli *et al*, 1943).

Virus may be spread by direct contact, as it can survive on the skin for several minutes (see p 628).

a serious outbreak affecting Eskimos 2 months after the annual visit of a trading ship Similar observations have been made in Newfoundland (Smyth, 1947) In lonely islands and other areas where communication is very limited, the infection may be spread by farm hands and others who move about from community to community (see Cheverton, 1937).

In Alaska, Pettit, Mudd, and Pepper (1936) could definitely trace the spread to lines of air travel Smillie (1930) reported an interesting outbreak in Labrador in 1928 The affected community was absolutely isolated from the outside world except through the visit of one member to a trading station This member returned

B infection occurred between 1938 and 1941, and probably between December 1941 and January 1942; this infection is probably endemic (Beveridge and Burnet, 1944). Sporadic B infections occurred in 1943 and 1945.

Differences in Behavior of Infections A and B

Infection with virus A usually results in epidemics or outbreaks, but infection with virus B is more frequently sporadic or subclinical. Nevertheless sporadic and subclinical infection with virus A can occur, and localized outbreaks or more widespread epidemics of B infection have been reported.

In 1945–6, B virus appears to have caused a number of small outbreaks in semi-isolated communities, particularly in younger persons (see, e.g., Dudgeon *et al*, 1946), Jackson (1946) recorded a number of outbreaks of B infection in service units where West Indians were selectively attacked.

As regards the periodicity of epidemic prevalences, it has been suggested that influenza A has a cycle of 2–3 years, while that of B is from 4–6 years (Commission, 1946 *a*). Stuart-Harris (1947) doubted, however, whether experience in Great Britain completely agreed with this theory.

Coexistence of Influenza A and B

Infection with viruses A and B may occur at the same time in a single epidemic, and certain persons may suffer recurrent attacks at short intervals, due to infection with the 2 strains (Lennette *et al.*, 1941; Hare, Hamilton, and Feasby, 1943; Vilches *et al.*, 1943 *a*, Burnet, Stone, and Anderson, 1946).

Antigenic Structure of Epidemic Strains

Apart altogether from the major antigenic differences between types A and B, lesser antigenic differences have been noted between strains occurring in a single epidemic. The concept is, therefore, advanced of the possibility of a number of related strains assuming epidemic spread at the same time (Burnet and Lush, 1940 *a*, Taylor and Dreguss, 1940 *b*, Magill and Sugg, 1943, 1944, Barnes, Morgan, and Finland, 1948).

Influenza Y

Observations in many countries have shown that during an epidemic of influenza proved due to virus A or B, 30–70 per cent. of cases, although clinically typical, fail to show serological evidence of infection, and no virus can be isolated from throat washings (Martin and Fairbrother, 1939, Brown *et al.*, 1941, Lennette *et al*, 1941, Pearson *et al*, 1941, Rudd, 1941, Taylor, Petrilli, and Dreguss, 1941, Hare, Auger, and McClelland, 1942, Taylor *et al.*, 1942–3, Burnet, 1943 *c*; Hare, Hamilton, and Feasby, 1943, Hare, Stamatis, and Jackson, 1943, Stansfeld and Stuart-Harris, 1943, Vilches *et al*, 1943 *a*, Silk, Menke, and Francis, 1944, Stuart-Harris, 1945 *a*, 1947, Sigel and Davis, 1947)

The explanation of influenza Y is obscure, but there are various alternatives (see Stuart-Harris, 1945 *a*)

1. There may be a type of influenza virus differing serologically from A and B, yet undiscovered—a virus that cannot infect experimental animals readily and is noninfective for eggs

The Commission on Respiratory Diseases (1946 *c*, *d*) drew attention to what appears to be a new disease that they call "acute undifferentiated respiratory disease" or ARD Epidemiologically, ARD has features distinct from influenza, and occurs in sharply defined outbreaks in the winter among new recruits. It is probably due to a transmissible agent (see Ch. LII)

2. These cases may be caused by the low-grade "basic" virus of Andrewes (see below).

3. These cases may be infected with the prevalent A or B strains but fail to

develop antibody response There is no reason, however, why such cases should not yield virus from washings.

Incidence of Attack

A usual attack rate in the more severe epidemics has been between 10 and 20 per cent. of the populace. Thus, Huber (1933) studied 5 epidemics in soldiers in New York, occurring in 1922, 1926, 1928, March 1932, and December 1932. He found that in the 1st epidemic 9 5 per cent. of the population was affected, but 20 per cent in the 5th Underwood (1934), studying over 17,000 persons in Leeds (England), found an attack rate of approximately 16 per cent In the 1936–7 epidemic in London, Blood (1937) reported an attack rate of 19 1 per cent in factory workers.

[illegible]

in children under 10. There has been no true peak in the young adult group, such as characterized pandemic influenza, since 1922 (see Collins, 1945)

Method of Spread

The main sources of infection are cases of the disease Cases are probably infective in the late incubation period as well as during the first few days of illness [illegible]

Influenza is essentially a droplet-spread aerial infection, and mice and human beings can be infected experimentally by inhalation Virus can persist in air for some hours, and it has been shown experimentally that it persists for a much longer time in a dry atmosphere than a moist one (Loosli *et al*, 1943, and see Ch. LX). Fomites may play a part in transmitting infection Virus can probably survive long enough on drinking and eating utensils to infect other persons, if the "washing-up" process is inadequate, mucoid material seems to preserve infectivity (see p 625). Virus can also survive in dust, fabrics, and materials (see p 625).

Hare and Mackenzie (1946) on the basis of experiments with *B. prodigiosus* suggest that important sources of infection are clothing and objects in the vicinity of the patient. The majority of exhaled particles falls downward onto the clothing and may be shaken off later, to be dispersed in the atmosphere, giving rise to infection in other persons These authors agree that infection may occur more directly by forcible expulsion of droplets as in sneezing, but suggest that indirect infection by dispersal of dried secretions is more likely. It has been shown experimentally that sweeping the floor of a room in which virus has been atomized increases the infectivity of the atmosphere for mice (Loosli *et al*, 1943)

Virus may be spread by direct contact, as it can survive on the skin for several minutes (see p. 628).

There are a number of observations pointing to the spread of infection by carriers apparently healthy; thus cases of influenza have broken out in an island or port following the arrival of a ship (see Cheverton, 1937) Høygaard (1939) described a serious outbreak affecting Eskimos 2 months after the annual visit of a trading ship Similar observations have been made in Newfoundland (Smyth, 1947) In lonely islands and other areas where communication is very limited, the infection may be spread by farm hands and others who move about from community to community (see Cheverton, 1937)

In Alaska, Pettit, Mudd, and Pepper (1936) could definitely trace the spread to lines of air travel Smillie (1930) reported an interesting outbreak in Labrador in 1928 The affected community was absolutely isolated from the outside world except through the visit of one member to a trading station. This member returned

home with influenza and soon the disease began to spread, ever-widening circles of contacts being involved Although it is often supposed that infection may be disseminated in public vehicles, the statistics of Blood (1937) in the London epidemic of 1936 did not support this contention. Greenwood (1944) has suggested that the present custom of working in cities and traveling to the periphery at night would favor the emergence of an infection such as influenza

It is often possible to trace the spread of the disease from town to town in a given country. Thus Gover (1936) has studied the direction of spread of 11 American epidemics since 1919 (see also Collins, 1930).

Influence of environment. Blood (1937) suggested that the factory and industrial worker is the first to be attacked in the community, and that there is a higher incidence of influenza in this class of worker. Earlier, Underwood (1934), however, had not found the same state of affairs, reporting that factory workers are less susceptible than clerks and outdoor workers.

Weather conditions Influenza epidemics occur mainly in the winter, but it is uncertain exactly how cold and wet act. It may be that damage to the ciliated nasal mucosa is of importance (Burnet and Clark, 1942). Underwood (1934) found that an increased incidence of influenza followed a drop in the temperature, particularly when there was associated fog.

Cheverton (1937) made the following interesting observations in the Falkland Islands (*a*) 48 hours before an outbreak there was a drop in barometric pressure (*b*) This was associated with a drop in the maximum temperature, and 24 hours later by a rise (*c*) In addition, 48 hours before onset there was a cold, damp, southeasterly wind, an increased rainfall, and little sun. (*d*) Also 72 hours before an outbreak he found a drop in the minimum temperature

The Origin of Influenza Epidemics

Influenza epidemics occur regularly in many parts of the world, and as seen above, virus A has an approximate 2–3 year cycle, whereas that of virus B is about twice as long. What mechanisms determine why an outbreak should occur, and how is the infection kept smoldering between epidemics? This subject has received attention from Andrewes (1942 *c*, 1946), and Stuart-Harris (1945 *a*), who draw attention to various possibilities

1 Influenza may tend to travel from country to country, so that an epidemic is usually imported Certainly there have been a number of reports, mentioned above, of influenza being imported into isolated communities, but as a rule influenza A tends to occur in Britain, Europe, and N America more or less simultaneously, without much evidence of importation of infection In 1945, however, there was evidence that influenza B started in June in Hawaii and spread east, giving rise to outbreaks in the Caribbean, N and S America, and particularly in Texas, there was then a slower spread through the U S. A Holland and Belgium were involved in December, and Britain in January Australia was involved in November The Australian and British strains were closely related antigenically, suggesting spread from a common focus (see also Dudgeon *et al*, 1946)

2 A second possibility is that influenza viruses are always present in the community, causing sporadic and subclinical infections in interepidemic periods There is no doubt that such subclinical infections do occur, and it would appear that this explanation is a likely one It is possible that the endemic and imported infections may at times be superimposed

3. It may be that influenza virus strains capable of causing widespread epidemics transfer to an animal host between epidemics The susceptibility of the pig is well known, and, as mentioned elsewhere, it has been suggested that the 1918 pandemic strain attacked this animal, producing swine influenza. Influenza virus can infect various rodents, and some such host may be postulated This theory is speculative, and there is little evidence that any such transfer occurs at the present day, even if

it did 30 years ago. It is difficult to see what factors would activate the virus in the intermediate host, and how the virus would then resume its human spread.

4. Influenza virus may exist in various phases, or grades, characterized by differing degrees of virulence for man and animals (Andrewes, 1942 *c*). Thus, Grade 1 virus is the basic, nonvirulent form. Such a virus may exist in interepidemic periods and be stimulated into increased activity by exogenous factors. In this connection the activation of swine influenza virus by injections of *H. suis* should be recalled A factor tending to increase the virulence of such a basic virus would be the existence of catarrh, facilitating exchange of upper respiratory flora. A virus so increased in virulence, Grade 2, could cause a mild form of influenza such as influenza Y. This type of virus would not be sufficiently virulent to be transmissible to experimental animals, accounting for the negative results in influenza Y. A virus of slightly greater virulence, Grade 3, would be transmissible with some difficulty to ferrets, and probably would not infect mice Grade 4 virus, still more virulent, would infect ferrets fairly readily, but mice with more difficulty. It is known that viruses with the properties of Grade 3 and 4 do occur in years of non-epidemic prevalence. Grade 5 virus would be readily transmitted to ferrets and mice, and would be responsible for the typical widespread epidemics occurring every 2–3 years Grades 6 and 7, of highest virulence, would be pandemic strains, 6 attacking chiefly young adults, and 7 being highly pneumotropic.

According to this attractive theory, outbreaks of influenza arise largely as the result of a mutation of the influenza virus to a greater degree of virulence.

5. So far we have been concerned chiefly with the properties of the parasite as an explanation of the origin of epidemics It is probable, though, that varying degrees of immunity of the human host also play some part in determining the onset of an epidemic. Burnet and Clark (1942) attach some importance to the antibody

1941) Stuart-Harris *et al.* (1938) found much higher rates in naval recruits as compared with older men Investigating the incidence in isolated Yorkshire dales, Pickles, Burnet, and McArthur (1948) suggested that there was evidence for a group of immunity lasting for 4 years and diminishing the attack rate.

In conclusion it would seem that the origin of influenza epidemics depends on a variety of circumstances, partly an increased virulence of a strain previously latent, partly on facilities for its rapid transfer, and partly on the degree of immunity of the population.

Preventive Measures

Needless to say, during epidemics all crowded places such as cinemas and theaters should be avoided. Children with influenza should be excluded from school, closure of schools may be of service in localities where the children live in widely separated homes, and will avoid contact one with another if they do not

demic prevalence, but this

, disinfection of the atmosphere of public buildings and vehicles by agents such as propylene glycol, or triethylene glycol (Robertson *et al.*, 1941, 1943) A mask soaked in iodine (which has a powerful action on the virus) may also prove of value (Stone and Burnet, 1945)

LABORATORY DIAGNOSIS

Methods for the laboratory diagnosis of influenza have been greatly improved of recent years, and a wide variety of techniques is now available

A. Isolation of Virus

Preparation of inocula.

Every attempt should be made to isolate the virus from patients, partly to establish the diagnosis of influenza, and partly so that the strain can be analyzed antigenically.

Virus is sought in garglings or throat washings, the patient being instructed to gargle about 10 c.c. of broth or saline. This can be mixed with 5 c.c. of broth, and roughly clarified by paper filtration. Such "raw" material can be inoculated intranasally in ferrets and other animals (see below); or a Gradocol membrane (APD 0.8 μ) filtrate can be prepared (Burnet and Foley, 1941 *a*). Hoyle (1944) recommends filtration through sintered glass filters (maximum PD 1.5 μ).

Filtrates can also be prepared from lung suspensions. Himmelweit (1943) rec- [illegible] issue suspensions at 3000 r.p.m. for 30 minutes, [illegible] 3 superimposed Gradocol membranes arranged [illegible] 1.5, 1.05 and 0.7 μ respectively). Alternatively a Berkefeld filtrate can be used, preferably obtained after preliminary clarification (Parker *et al.*, 1946).

Certain workers have attempted to concentrate any virus present in throat washings. Thus washings can be treated with red cells to adsorb virus, and after 8–10 minutes zephiran (1/20,000) is added to keep down contaminants. After 25 minutes the cells are spun down, and then resuspended in 1 c.c. of saline which is available for inoculation in eggs (*U.S. Nav. Med. Lab.*, 1946).

Alternatively the garglings are centrifuged for ½ hour at 12,000 r.p.m. to throw down organisms. Human O cells are added to the supernatant to a final concentration of 1 per cent. Finally the red cells plus adsorbed virus are spun down and resuspended in 1 c.c. saline which can be injected in eggs (*U.S. Nav. Med. Lab.*, 1946).

More recently, antibiotics have been added to new material prior to inoculation.

If it is not convenient to examine throat washings immediately, they can be stored for several months in the cold, preferably at −76° C (Francis *et al.*, 1937 *a*, Hirst, 1942 *b*, Taylor and Parodi, 1942).

Inoculation of ferrets and hamsters.

Virus was originally isolated by the Hampstead and other workers by nasal instillation of ferrets, and this method should still be tried whenever possible (for technique and clinical features see section on ferret, below). Ferrets should be inoculated with clarified garglings or Gradocol filtrates. It is usual to pass suspensions of turbinates or lungs 3–5 times before regarding a result as negative.

As emphasized by Andrewes and mentioned above, virus strains vary greatly in their infectivity for ferrets. Typical epidemic strains of virus A usually can be established without much difficulty, but strains recovered in interepidemic periods may be difficult to establish, even by "blind" passage (Burnet and Lush, 1940 *a*, Lennette *et al.*, 1941, Taylor and Dreguss, 1941, Andrewes, 1942 *c*, Andrewes and Glover, 1944). B strains seem to be difficult, and often impossible, to adapt to ferrets (Eaton and Beck, 1941, Taylor *et al.*, 1942–3, Dudgeon *et al.*, 1946; Hirst, 1947 *b*).

Hamsters can largely replace ferrets, and after passage, strains can be passed to mice (Taylor, 1940, Lennette *et al.*, 1941, Taylor and Parodi, 1942, Taylor *et al.*, 1942–3, Eaton *et al.*, 1945).

Instead of killing ferrets or hamsters, and passing their tissues, the animals may be bled 2 weeks after intranasal inoculation of washings, and their sera examined by any of the recognized methods for neutralizing or CF antibodies (Magill, 1940, Hirst, 1942 *b*, 1945, Taylor and Parodi, 1942, Parodi, Pennimpede, and Vilches, 1944, Eaton *et al.*, 1945).

Inoculation of mice.

As a general rule, it is not possible to pass influenza virus direct from man to mouse by nasal instillation of garglings (Andrewes, Laidlaw, and Smith, 1935, Burnet and Lush, 1940 *a*, Mulder, 1940 *a*, Taylor and Dreguss, 1941). Some workers have, however, achieved success when lungs are passed in series (e.g., Sulkin, Smith, and Douglass, 1941; Sulkin, Bredeck, and Douglass, 1942; Forster and Shaughnessy, 1946, and see p. 601).

The ease of adaptation of ferret-passaged material to mice varies considerably, and strains in Andrewes' low grades may not infect mice at all Generally after a few ferret passages virus can be passed fairly readily to mice (Burnet and Lush, 1940 *a*, Magill and Sugg, 1943; Andrewes and Glover, 1944) Japanese workers have claimed the isolation of strains from centrifuged washings in mice blockaded with India ink (Tsurumi, Ogasawara, and Fujil, 1941). B strains isolated in eggs by Dudgeon *et al.* (1946) could not be adapted to mice (see also Burnet and Stone, 1946, Hirst, 1947 *b*).

Instead of attempting the isolation of virus by passing suspensions of mouse lungs, some of the animals inoculated intranasally with paper filtrates of garglings can be bled after 14 days and their sera tested for antibody, the remainder of the batch can be tested for the development of the immune state by the inoculation of a stock strain (Burnet and Foley, 1941 *a*).

Other animals.

According to Weir (1944) cane and bush rats can also be used

Inoculation of eggs.

The fertile egg has been widely used in the isolation of influenza viruses from raw washings, filtrates, or washings treated with antibiotics and antiseptics (For details of the changes produced in the fertile egg see the appropriate section below) In general, evidence of infection is obtained by the presence of chick cell agglutination with the egg fluids, or by the pathological changes present in the embryo

Eggs may be inoculated with filtrates in the yolk sac (Beveridge, Burnet, and Williams, 1944), or on the chorio-allantoic membrane (Chapman and Hyde, 1940), but these routes are not much used

Allantoic inoculation is more widely employed

(*a*) Raw washings (0 2 c c.) can be inoculated without any treatment, influenza virus will develop in a proportion of the eggs even if bacterial contaminants grow also (Thigpen and Crowley, 1943; Adams, Thigpen, and Rickard, 1944, Crowley, Thigpen, and Rickard, 1944, Rickard, Thigpen, and Crowley, 1944, 1945, Eaton *et al* 1945, Hirst, 1945, *U.S. Nav Med. Lab.*, 1946).

(*b*) Such raw washings can be treated with penicillin (*Hirst, 1945, Rose, Millow, and O'Neill*, [illegible] 1946), penicillin and sulfonamides [illegible] Anderson, 1946), or streptomycin [illegible] Ienle *et al.*, 1946 *a*) or Zephiran, 1/20,000 (*U.S Nav Med Lab*, 1942 *a*) can also be added to the raw washings, which are inoculated after 15–20 minutes contact

(*d*) Gradocol filtrates can be used.

After inoculation by any of the above methods, allantoic fluid is tested for virus by the chick cell agglutination technique (see Ch LXI). If the result is negative, the fluid should be passed through 3–5 more series of eggs Hirst (1947 *b*) found that B strains were not easy to adapt to the allantoic cavity.

Amniotic inoculation is probably more sensitive than allantoic inoculation, and as shown by Burnet (1940 *a*, *b*) is an excellent method of isolating virus As some

embryos fail to show evidence of infection, 6 should be inoculated with each sample.

(*a*) Raw washings treated with penicillin (Hirst, 1945, Francis, Salk, and Brace, 1946), or penicillin and sulfonamides (Burnet and Stone, 1945 *c*, Burnet, Stone, and Anderson, 1946, Dudgeon *et al.*, 1946) may be inoculated (0.1 c c.). McKee and Hale (1947) recommend 500 units of penicillin and 1000 units of streptomycin per c c. These are perhaps the most satisfactory methods of laboratory diagnosis in influenza.

Burnet and Stone (1945 *c*) recommend the following technique: The patient gargles 10 c c of saline for one minute, 5 c.c. of broth is then added, and enough penicillin to make a final concentration of 100 Oxford units per c.c. This material is filtered through sterile filter paper to remove gross particles Amniotic inoculation with 0 1 to 0.25 c c. of washings is then performed in 13–14 day embryos, 0.1 c c. of 5 per cent. sodium sulfadiazine being first inoculated in the same cavity. Embryos dying before 48 hours are discarded.

(*b*) Chemicals, as mentioned above, may be used.

(*c*) Most work has been carried out with Gradocol (APD 700–750 mμ), or similar bacteria-free filtrates (Burnet and Foley, 1940, 1941 *a;* Rudd, 1941, Stuart-Harris, 1941; Burnet *et al*, 1942, Hirst, 1942 *b*, 1943 *b*, 1945; Burnet and Bull, 1943; Burnet, Beveridge, and Bull, 1944; Beveridge, Burnet, and Williams, 1944, Hoyle, 1944; Eaton *et al.*, 1945; *U.S. Nav. Med. Lab.*, 1946).

The presence of infection is shown by chick cell agglutination given by the amniotic or allantoic fluid, and by the characteristic tracheal exudate and lung changes (see p. 620). If the first passage proves negative, passages should be continued with allantoic fluid, amniotic fluid, or ground lung or trachea (10 per cent. suspensions). Virus B may be less easy to isolate than virus A, but sometimes seems to grow better in 8–10 day embryos, a number of Australian B strains in 1945 was however, isolated in 13–day eggs (Beveridge and Burnet, 1946) Hirst (1947 *b*) found that it was necessary to passage to isolate B strains It must be remembered that normal amniotic fluid after about the 13th day causes agglutination of various red cells, but not of chick cells, the titer, however, is not above 32 (*Commission*, 1946 *b*). Some normal allantoic fluids of high protein content give an atypical agglutination of guinea-pig cells, but not beyond 1/10 (Beveridge and Burnet, 1946).

Inoculation of tissue cultures.

It has been claimed that virus can be isolated by inoculation of tissue cultures (see p 616)

B. Serological Tests

A sample of patient's serum should be obtained during the acute phase of illness, and a further sample 2 weeks later Both samples are then tested at the same time for a rise in virus neutralizing, agglutination inhibiting, or complement fixing antibodies (see Ch LXIII) A twofold, and certainly a fourfold increase in antibody titer indicates infection It should be realized, however, that a number of cases of undoubted influenzal infection, especially those with a high initial titer, will fail to show any increase in convalescence

C. Blood Picture

With regard to the blood picture, leukopenia was usually found in pandemic, and may occur in epidemic influenza (Burden, 1933, Reyersbach, Lenert, and Kuttner, 1941), *especially when secondary infection depresses hemopoiesis* (Parker *et al.*, 1946) Usually, however, the count is relatively normal (Stuart-Harris *et al*, 1938, Stuart-Harris, 1945 *a*, Adams, Thigpen, and Rickard, 1944) It appears that uncomplicated influenza may be accompanied by a leukocytosis (Scadding, 1937, Parker *et al.*, 1946).

CHAPTER LVI

ANTIGENIC CHARACTERISTICS OF INFLUENZA VIRUS

ISOLATION AND STRAINS OF INFLUENZA VIRUS

Early Work

THE VIRUS now known as Type A was originally isolated by the National Institute

36–7 (Smith,

aidlaw, 1935;

isolated this

ated in Mel-

France (Du-

with A and B virus according to the infection present. We refer to viruses A or B as "types," and individual strains belonging to either type as "strains"

Attempted Isolation in Interepidemic Periods

As explained above, the clinical features of influenza, although characteristic, do not always enable a differentiation to be made from other infections of the respiratory tract Virus is not usually recoverable from cases with influenzal symptoms

1935, Fair-

umotropic"

Strains of Virus

The following are the best known strains of virus A· WS, PR8, Philadelphia, Leningrad, Melbourne, Christie, Talmey, Weiss, Bel, and CC

The best known strains of virus B are Lee, TM (Magill and Tyndall, 1941), Montgomery (Eaton and Beck, 1941), Paddington (Himmelweit, 1943), Bon (Burnet, Beveridge, and Bull, 1944). A number of other B strains has also been studied (Eaton *et al*, 1942, Gordon, 1942, Francis, Salk, and Brace, 1946, Burnet, McCrea, and Stone, 1946, Burnet and Stone, 1946, Dudgeon *et al*, 1946, Francis, 1947 *a*).

ANTIGENIC STRUCTURE OF INFLUENZA VIRUS

The antigenic structure of influenza virus is complex, and has been much studied of recent years. Most of the information has been obtained by differential centrifugation, serological tests (especially complement fixation and the chick cell agglutination test), and electron microscopy. These subjects will all be dealt with later in appropriate sections, but it has been thought desirable to bring together in this section all observations relating to the structure of influenza virus.

[1] References are appended at the conclusion of Ch LXIII, p. 671 et seq

First suggested by the work of Smith (1936), Hoyle and Fairbrother demonstrated conclusively that influenza virus was of complex structure, using mouse lung suspensions (Hoyle and Fairbrother, 1937 *b*, *c*, Fairbrother and Hoyle, 1937 *b*, Fairbrother, 1938). By differential centrifugation they separated 2 fractions, the elementary body (EB) and the soluble substance (SS). They were able to show that these 2 substances have very different properties: The EB's are associated with infectivity. They stimulate resistance to infection in mice. Virus neutralizing, and to a lesser degree complement fixing, antibodies develop after their injection. Even when EB's are rendered noninfective by heating at 57° C., mice and ferrets can still be immunized.

The soluble substance they found to be noninfective. On injection into mice it fails to stimulate resistance to infection, virus neutralizing antibodies do not develop, and complement fixing antibodies only to a slight extent. The soluble substance acts as a powerful antigen in complement fixation tests, and is found abundantly in the supernatant fluid of saline extracts of lung.

These observations have since been confirmed and extended by other workers, many of whom have used infected allantoic fluid as source of virus, rather than lung suspension (Eaton, 1940 *a*, Lennette and Horsfall, 1940, 1941, Chambers and Henle, 1943, Chambers *et al.*, 1943, Friedewald, 1943; Friedewald and Pickels, 1944, Henle and Wiener, 1944, Henle *et al*, 1944, Lauffer and Miller, 1944 *b*; Stanley, 1944 *a*, *b*, Hoyle, 1945; Wiener, Henle, and Henle, 1946, see also section on centrifugation below)

When preparations containing influenza virus A or B are centrifuged, the elementary bodies are thrown down at a lower speed than the soluble substance (SS). The EB's have a sedimentation constant of about 600 S, and that of the soluble substance is about 30 S, there is also a 3rd component known as < 30 S (Henle and Wiener, 1944, Henle *et al*, 1944; Stanley, 1944 *b*, Wiener, Henle, and Henle, 1946, see also section on centrifugation below). The properties of these 3 components are as follows

Elementary Bodies, or 600 S Component

1. The size of these particles, calculated from centrifugation data, is 80–120 mμ.
2. They are associated with infectivity.
3. They cause red cell agglutination.
4. They produce toxic lesions in mice.
5. They produce the interference phenomenon
6. They can immunize animals, which develop virus-neutralizing and other antibodies and resist infection

Antibodies to 600 S develop in man after both infection and vaccination (Wiener, Henle, and Henle, 1946) Absorption of antisera with 600 S removes their ability to react with 600 S in the CFT, capacity to inhibit chick cell agglutination, and to neutralize mouse infectivity (Wiener, Henle, and Henle, 1946)

7. EB's act as an antigen in complement fixation
8. EB's cannot be entirely freed from SS by washing, and it appears that they are partly composed of SS (Lennette and Horsfall, 1940, Hoyle, 1945). Experiments with absorbed antisera have shown that 30 S is part of 600 S (Wiener, Henle, and Henle, 1946)
9. SS is released from 600 S by partial disintegration (Henle and Wiener, 1944), and sonic vibration (Wiener, Henle, and Henle, 1946) The amount of SS in the elementary bodies varies with different strains (Stanley, 1944 *b*)
10. EB's probably contain 3 or 4 antigenic components as well as SS (Hoyle, 1945). Some of these components are shared by related strains, but others may be specific (Friedewald, 1943, Henle and Wiener, 1944, Wiener, Henle, and Henle, 1946) Antigenic differences between strains of one type are thought to be due to quantitative rather than qualitative variations in antigenic components

11. The complement fixing property of the elementary body can be adsorbed by fowl cells and eluted therefrom, and cannot be separated from the virus by repeated washings or adsorptions (Friedewald, 1943).

Soluble Substance or 30 S Component

Soluble substance is found most abundantly in the supernatant fluid of mouse lung suspensions, and can also be obtained b [illegible] fluid It can be found in saline extracts of [illegible] Fairbrother, 1937 *c*), but very little is foun [illegible] and Horsfall, 1941) *The properties of soluble substance are as follows* [illegible]

1. The component is thrown down by a speed of 30,000 r.p.m., and the size of the particles is about 10 mμ (Lennette and Horsfall, 1940, Henle and Wiener, 1944; Stanley, 1944 *b*).
2. This component is not associated with infectivity, apart from occasional contamination with 600 S particles
3. It does not agglutinate red cells, and is not adsorbed by them
4. It does not give toxic lesions in mice
5. It does not produce the interference phenomenon
6. Antibodies to 30 S develop in man regularly only after infection, not after vaccination (Wiener, Henle, and Henle, 1946)
7. SS acts as a powerful antigen in the complement fixation test.
8. The soluble substances of various strains of virus A appear to be identical and distinct from those of virus B, SS appears to be a single antigen (Lennette and Horsfall, 1941; Friedewald, 1943, Henle and Wiener, 1944; Hoyle, 1945, Wiener, Henle, and Henle, 1946).

The SS of swine virus resembles, but is probably not identical with that of virus A (Lennette and Horsfall, 1941).

< 30 S Component

This component behaves serologically like 30 S, and remains suspended even after repeated centrifugation at 30,000 r.p.m It gives complement fixation, and appears to consist of a single antigen (Henle and Wiener, 1944).

"Normal" Components in the Structure of Influenza Virus

As so much work has been performed with preparations of influenza virus from infected allantoic fluids, it is necessary to inquire whether normal allantoic antigen may not enter into the structure of the virus. Such is, in fact, the case Thus Knight (1944 *c*) isolated a macromolecular "protein" material by high speed centrifugation from normal allantoic fluid The yield was maximal after 14 days incubation at 39° C (about 0.02 mgm per c.c of fluid) The properties of this material were

1. It contained protein, carbohydrate, lipoid, and *in general the composition* resembled that of purified PR8 virus
2. The isoelectric point was pH 2.3, whereas that of virus is usually *around 5.*
3. The normal material had a variety of sedimentation constants *depending on* the concentration and viscosity of the fluid The sedimentation of the *major component* was 170 S
4. The diameter of the predominant particles, *shown by electron micrographs,* *was about 40 mμ, whereas influenza* virus measures about 100 *mμ.*
5. The normal protein did not agglutinate *chick red cells and was not absorbed* by them
6. The normal protein was a good antigen, and *antiserum could be prepared in*

rabbits. Precipitin tests showed that preparations of influenza virus, purified by centrifugation of infected allantoic fluid, contained normal protein material. This normal material could not be removed by repeated freezing and thawing of allantoic fluid and repeated adsorption of virus on to red cells.

7. From 2 virus strains (F12 and Lee) a small component, closely related to or identical with normal protein, was separated by centrifugation.

8. Antisera to the purified normal material inhibited red cell agglutination by A and B strains at serum dilutions of 600–700, whereas antisera to purified PR8 inhibited at 112,000. Antiserum to normal protein did not show any neutralizing effect in chick embryos or mice.

Knight (1946 *b*) later extended this work, and confirmed that the best preparations of virus from allantoic fluid now available are still grossly contaminated with nonviral material. In these later studies he obtained purified preparations of sedimentable normal allantoic protein. Purified virus preparations were obtained by adsorption to and elution from chick red cells, followed by centrifugation. Particles from normal and infected mouse lungs were also used. Antisera were prepared to these various normal and infective particles in rabbits, and precipitin tests performed, with the following results:

1 With antiserum to normal allantoic protein, heavy precipitates were obtained with highly purified PR8 and Lee strains from allantoic fluid. No precipitate was, however, obtained with PR8 particles from mouse lungs. Highly purified preparations of PR8 and Lee viruses from allantoic fluid contained about 20 per cent. and 30 per cent. respectively of normal protein

2. With antiserum to purified PR8 from allantoic fluid, precipitates were yielded by homologous antigen, normal allantoic protein, Lee virus from allantoic fluid, and PR8 from mouse lung. Normal lung particles gave no significant precipitate

3. The antibodies in PR8 antisera responsible for cross precipitation with Lee virus did not neutralize the infectivity of Lee virus.

4 About 96 per cent. of the infectivity of the most highly purified allantoic virus preparations could be precipitated by antiserum to normal allantoic protein

5 After a single chick embryo passage, mouse lung virus became indistinguishable from egg-adapted virus in precipitin tests, showing that it acquired an antigenic component from the new host.

In later work (1947 *a*) on the chemical structure of PR8 and Lee strains, he suggested tentatively that glucosamine might be derived entirely from the host, if this assumption was correct, a revised estimate of the amount of normal host material present in PR8 and Lee particles would be 59 per cent. and 78 per cent. respectively

This important work of Knight shows that host antigen–mouse or chick, for example–is incorporated in the intimate structure of the virus particles Knight suggests that there is a common antigenic component for a given strain of virus present in all hosts In addition to this intrinsic virus fraction, each host yields a component of its own Antibodies to the viral component neutralize virus infectivity, and inhibit agglutination of chick red cells by virus, irrespective of the source of the preparation of virus acted upon

Wiener, Henle, and Henle (1946) found that Knight's normal allantoic protein did not react in fixation tests with human convalescent sera

Francis' "Complex Antigen"

Francis (1947 *a*), who has studied the effect of heat on the hemagglutinating capacity of influenza virus B strains in agglutination inhibition tests (see p 637), has postulated the presence of a complex antigen consisting of a heat-stable component and a heat-labile component The precise relationship of these observations to those already mentioned is not at present clear.

ANTIGENIC DIFFERENTIATION OF TYPES AND STRAINS OF INFLUENZA VIRUS

Methods

Preparations of the virus to be analyzed can be obtained from mouse lung, if necessary, EB's and SS can be obtained by suitable differential centrifugation. It is often more convenient to make use of the susceptibility of the allantoic and amniotic cavity to yield a generous sample of virus-containing fluid

As regards antisera, rabbit sera have been much used, but are probably not so specific as ferret sera. Serum is obtained from rabbits after 1 or 2 intraperitoneal injections of living virus, if more virus is given, the antibody response tends to be too "wide." Ferret sera obtained about 2 weeks after experimental infection are highly specific. Human sera are not usually sufficiently specific for this type of work. Burnet and Stone (1946), however, in work with B strains, used the sera of adolescents, they applied a correction to the crude antibody titers to allow for the differing avidities and varying antibody content. The sera of fowls have been recommended, being removed 15 days after an intraperitoneal inoculation of virus (Hudson, Sigel, and Markham, 1943). Mouse sera have also been employed (Eaton, 1941)

1 As regards the tests used, the unknown strain can be exposed to the action of sera prepared against known strains, and the mixtures tested for infectivity by mouse inoculation, or inoculation in eggs or tissue cultures The known strain is tested likewise, and an estimate of their affinity can be expressed on a percentage basis

2 Complement fixation tests can also be carried out, preferably separately with antigens prepared from EB's and SS of the unknown strain, and appropriate known antisera

3. Passive protection experiments with antisera to known strains have also been used, the unknown strain being inoculated nasally in a susceptible animal.

4. The precipitin test was used in Knight's work (see above), but is of little use in differentiating between strains. Tests involving absorption of antibodies can be used in accurate work (Ch. XI).

5. It is now customary to use the chick cell agglutination test in analyzing the antigenic structure of an unknown strain (Hirst, 1942 *b*, *c*, 1943 *b*, see Burnet and Clark, 1942). Thus, the unknown strain is mixed with known antiserum in the presence of chick cells If agglutination occurs, then the unknown strain differs from the strain used to prepare the serum; if there is no agglutination, an antigenic similarity can be inferred. If the known immune serum is titrated in the presence of the unknown strain, and a parallel test set up with the known serum and known strain, it is possible to assess how nearly the unknown strain resembles the known. In accurate work it may be necessary not only to investigate the antigenic structure of the EB's by the chick cell test, but also of the SS by complement fixation It may also be necessary to prepare antiserum to the EB's and use this serum in tests with known strains. Hirst's method has the advantage that it is not necessary to use mouse-adapted strains of virus, it can, therefore, be carried out quickly with antigen derived from allantoic fluid in the first or early passage from the human material

6 Another type of test involves active immunization of mice with known strains, and subsequent challenging with the unknown, *vice versa*, the unknown can be used to immunize, and the known to challenge Antigenic differences be-

[illegible] a single previous

strain of influenza

Inoculate the amniotic cavities of 4 to 6 12-day chick embryos with a Gradocol filtrate of throat washings.

Inoculate mice intranasally with amniotic fluid from those embryos showing typical changes.

Bleed some of these mice, and test for the amount and type of influenzal antibody against known strains. Test the resistance of the remainder by the inoculation of a standard adapted mouse strain intranasally.

Virus A

For a time it was thought that all strains of influenza virus were antigenically similar. For instance, Francis (1934–5) found that the sera of ferrets convalescent from infection with either his PR8 or Phila strains neutralized both the homologous and heterologous strains. Andrewes, Laidlaw, and Smith (1935) isolated 6 new strains and found them serologically identical Brightman (1936) found that his New Haven strain was neutralized by antisera to PR8 and Phila strains. Stokes *et al.* (1937 *b*) found that 3 strains isolated in Philadelphia were neutralized by antiserum to the PR8 strain. French strains studied by Dujarric de la Rivière and Chevé (1937 *b*) all appeared to be identical serologically with the WS and PR8 strains.

Later results, however, conclusively showed that antigenic differences do exist between certain strains. Thus, Magill and Francis (1936–7) found a difference between their PR8 and Philadelphia strains by the use of rabbit antisera. Burnet (1937 *b*), who studied the question in detail, was able to divide strains into 3 groups on the basis of antigenic differences (*a*) the New World type consisting of Melbourne, *Phila*, and *PR8* strains, (*b*) the Old World type consisting of WS, BH, Moscow and Leningrad strains; (*c*) swine influenza virus. In grouping these strains he used neutralization tests with convalescent ferret serum in mice and on the chorio-allantois, active immunization of mice and ferrets, and antibody-absorption.

Stuart-Harris *et al* (1938) found that strains isolated in 1936–7 were different antigenically from those isolated in earlier epidemics. Francis (1938) carried out another study of this problem, using serum neutralization tests and active immunization of animals He found that the majority of 1936–7 strains was closely related one to another, but differed from the earlier strains. Further, he made the important observation that strains of different antigenic constitution might occur in the same epidemic.

Certain papers established beyond all question the antigenic heterogeneity of influenza virus A strains (Magill and Francis, 1938 *a*, Francis and Magill, 1938 *a*, Smith and Andrewes, 1938, Andrewes, 1939) In this work immune sera were used to detect antigenic differences, and so were experiments involving active immunization and serum protection of mice In addition, it was possible to show that serum antibody could be demonstrated by its effect in preventing the growth of virus in tissue culture (Magill and Francis) The most important findings of these groups of workers may be summarized as follows

1. Twenty-eight different human strains were examined by Smith and Andrewes, and 23 by Magill and Francis

2. The strains that resemble each other most closely are those from the same epidemic, different serological types may be isolated from the same epidemic (Magill and Francis)

3. Variations between strains cannot be accounted for by the effect of animal or tissue culture passage (Magill and Francis)

4. There are numerous antigenic components shared by influenza strains, and these may be considered as arranged in the form of a mosaic, the components are present in different proportions in different strains, all the components are not present in every strain (Magill and Francis, Smith and Andrewes)

5 Four components are of major importance, strains may be classified, on the

basis of these components, into 3 groups of highly specific, relatively nonspecific, and intermediate strains (Smith and Andrewes).

Other more recent observations on the antigenic differentiation of virus A strains may be quoted Thus, Hungarian strains were found to differ considerably from PR8 and WS, and to fall into a group of their own (Taylor, Dreguss, and de Ritis, 1940, Taylor and Dreguss, 1941)

Hirst (1943 *b*) analyzed 18 A strains isolated in the 1940–1 U.S epidemic, 16 appeared to belong to one group while 2 were distinct.

Friedewald (1944 *b*) studied the following strains of virus A by antibody absorption tests PR8, Christie, Talmey, WS, and the swine strain He found that PR8 had the broadest range of specific antigenic components, the other strains being more specific.

Sugg and Magill (1946) detected differences between the CC and WS strains by challenge tests in actively immunized ferrets

With regard to the effect of passage on antigenic structure, it has been shown that specific strains may change on mouse passage to less specific intermediate forms (Burnet and Lush, 1940 *a*) An antigenic difference could be made out between Melbourne Egg virus and its substrain adapted to mouse passage (Burnet and Bull, 1944). It has been found that there is an antigenic difference between a line of PR8 virus passed continually in the mouse, and another line of PR8 passed in tissue cultures and eggs (Francis, 1947 *c*)

The main observations in this connection concern the O–D change that occurs in virus on egg passage, and which is fully discussed in a separate section below.

Our present knowledge of the structure of influenza virus A enables us to understand more clearly the position in regard to antigenic differentiation between strains From what has been said above, it will appear that all strains are composed of elementary bodies and soluble substance The elementary bodies contain a number of antigenic components that may be shared by strains of the same type Differences between strains of the same type of virus are largely due to quantitative differences in antigenic components Differences between Type A and B ...
due to qualitative d
a proportion of SS
distinct from the SS of virus B Finally, all EBs contain from 20–30 per cent of antigenic material derived from the animal host or chick, at least

Virus B

Strain differences were already well recognized when Francis (1940 *a, b*) reported that he had isolated a virus (Lee) of the influenza group so distinctive anti-

those of virus A The SS of B strains is also distinct from that of A strains Both B and A strains contain a definite proportion of antigenic material derived from the host, as shown by Knight, which may account for an apparent antigenic relationship between the 2 strains

Strain differences occur with virus B just as with virus A (Gordon, 1942, Burnet, Beveridge, and Bull, 1944) Thus strains isolated in England and Australia, and in other parts of the world in 1945–6 were found to resemble each other closely and to differ from the Lee strain (Burnet and Stone, 1946, Dudgeon *et al*, 1946).

Work of Hirst (1947 *a, b*)

Recent work of Hirst suggests that the whole question of the antigenic structure of influenza viruses needs reinvestigation It appears that previous conclusions,

based on cross protection experiments with ferrets or mouse-adapted virus, regarding minor antigenic differences between strains of one type, may have been mislead[illegible], and studied antigenic structure by means of

[illegible] ntigenic structure, changed on mouse passage, so that they differed not only from one another, but from the parent also.

2. None of a number of B strains isolated in 1945 in Hawaii, Yale University, and New York differed significantly from any of the others, these strains showed distinct differences, however, from mouse-adapted Lee (B) virus

3. Confirming earlier observations made in 1940–41, Hirst found no significant antigenic differences between A strains isolated in 1943–44 from 4 different states. A slight difference was detected between A strains isolated in 1940–41, and in 1943–44.

4. He emphasizes that present conceptions of strain differences, based on mouse work, are probably inaccurate, for when egg-adapted viruses have been used, no significant antigenic differences have been revealed. It would seem logical to replace current vaccines containing mouse-adapted strains (PR8, Weiss, and Lee) by strains *as similar as possible to those current in human epidemics.*

Swine Influenza Virus

The relationship between swine and human strains has been investigated by various means Thus the sera of swine convalescent from swine influenza do not neutralize the human strain of virus A *in vitro* (Francis, 1934–5). Further, Francis and Shope (1936) reported that the sera of animals recovering from infection due to human or swine viruses were virtually specific, for little neutralization of the heterologous virus took place They found that hyperimmunization with human virus A resulted in the production of antibodies operating against the swine virus as well, whereas hyperimmunization with the swine virus only increased the human virus antibody irregularly. They concluded, therefore, that although the 2 strains were immunologically distinct they shared antigenic components Further, the common antigen was present in greater quantity in the human virus Using the complement fixation technique, Fairbrother and Hoyle (1937 *a*) also postulated a common antigen in the 2 strains A similar conclusion was arrived at by Magill and Francis (1938 *a*) and Francis and Magill (1938 *a*), using cross neutralization and cross immunization tests in mice Shope (1939), using rabbit antisera in neutralization tests, was able to distinguish human and swine strains readily

The common antigenic factor gives rise to some cross immunity when the resistance of animals recovered from the infection is tested by heterologous virus.

Thus, Shope (1937 *a*) found that swine recovered from swine influenza, or the virus infection only, are generally resistant to a latter inoculation of human influenza virus A He also found that swine recovered from infection with the virus of human influenza and *Hemophilus influenzae suis* are generally immune to swine influenza The human virus infection itself (without the bacterium) does not, however, confer immunity to swine influenza.

Investigating the nature of the immunity in those pigs that had been infected with swine virus, Shope found that it was really a refractory state The human virus was unable, in these resistant animals, to penetrate the nasal mucosa of the pig. The immunity was not due to antibodies, as swine recovered from the swine virus did not show antibodies to the human virus In distinction to this mechanism, Shope found that the mucosa of swine recovered from the human infection did allow the swine virus to pass through, the virus was, however, dealt with by other mechanisms

The antigenic structure of strains of swine influenza virus isolated in Great Britain has been investigated Glover (1941 *a*) found that they were rather different from American strains, and not so clearly distinct from human strains (see also Glover and Andrewes, 1943). Confirmatory results were obtained by Hudson, Sigel, and Markham (1943), who compared them with PR8 and WS (A), Lee (B), and Shope's swine strain They used specific inhibition of chick cell agglutination, and sera obtained from ferrets and fowls The British strains were found to be closely related to PR8 and WS and distinct from Shope's virus

RELATIONSHIP TO OTHER VIRUSES

Influenza virus has highly characteristic properties and does not resemble many other viruses, although a number share the ability to agglutinate red cells

THE O-D CHANGE

Burnet and his collaborators have drawn attention to differences in the properties of virus as freshly isolated from the host by amniotic inoculation, and the same strain after it has been passed in the laboratory. The freshly isolated virus is said to be in the O (original) phase, while the stock virus is in the D or derivative phase. D phase virus develops when strains are passaged through and adapted to eggs by the amniotic, yolk sac, or allantoic routes, unless special precautions are taken. The change that occurs is considered to be in the nature of a discontinuous

Sources of O Phase Virus

O phase virus is isolated most readily from the human case by inoculation of washings in the amniotic cavity. It has also been recovered from the nasal washings of a ferret inoculated with first passage virus (Burnet and Stone, 1945 *c*).

Strains Used

The original work was carried out with strain Bel of Type A (Burnet and Bull, 1943, Burnet and Stone, 1945 *b*) Other A strains have been isolated in the O phase (Beveridge, Burnet, and Williams, 1944; Burnet, McCrea, and Stone, 1946, Hirst, 1947 *b*).

Burnet and Bull (1944) reexamined the properties of their strain Melbourne Egg (Type A). In the early stages of chorio-allantoic passage this strain showed D hemagglutination, but in its fully developed form it resembled closely an unadapted O strain

Burnet, Beveridge, and Bull (1944) studied the properties of a strain Bon of Type B They could not demonstrate any change from the unadapted to the adapted state. Other B strains isolated by amniotic inoculation have shown no evidence of being in the O phase (Burnet, Stone, and Anderson, 1946, Dudgeon *et al.*, 1946)

Properties of the Various Phases

1 O strains in amniotic fluid do not readily agglutinate fowl cells, but human

of fowl cell ag-

) and D phases is not quite so clear cut. An almost continuous series of reactions can be observed among amniotic fluids or lung emulsions from embryos infected with O phase virus at various dilutions (Burnet and Stone, 1945 *b*). As now defined, therefore, O virus preparations show no fowl cell agglutination, or at most a titer less than 1/20 of that given by guinea-pig cells Two intermediate grades are now recognized— α and δ The F/G ratios, and the character of the deposited agglutinated red cells are as follows

O	No agglutination	F/G ratio 0/40–0/1,000
ω̄	Weak loose, rapidly disappears	1/20–1/3
δ	Streaky or insular	1/3–1
D	Continuous shield	1 or +

The agglutination reactions with red cells from various species are as follows

	O	D
Fowl	not readily	readily
Guinea-pig	equally well agglutinated	
Human	equally well agglutinated	
Pigeon	equally well agglutinated	
Ferret	very weakly agglutinated	
Mouse	very weak	readily

It must be noted that normal amniotic fluid after the 13th day contains pseudo-globulin from the albumen sac, and this can cause agglutination of guinea-pig and many other cells, but not above a titer of 32, chick cells are not agglutinated (Commission, 1946 *b*).

2. When O phase virus is inoculated in the amniotic cavity, the amount of fluid is found to be increased, but this increase does not occur with D phase, where, in fact, the volume may be reduced Multiplication of O virus is more rapid in 13–14 than 12-day embryos O virus does not usually kill the embryo in small doses within 4 days, fully adapted D strains usually kill in 2–3 days (Beveridge and Burnet, 1946).

After inoculation of O virus in the amniotic cavity, it can be recovered in this phase for the first 2–3 days, but thereafter intermediate D type virus is usually recovered After the 5th day, no typical O virus is recoverable. As a general rule, virus is recovered in the same phase in both lung and amniotic fluid

If concentrated preparations are inoculated amniotically, D phase virus results, whereas if dilute inocula are used, the amniotic fluid may give the reactions characteristic of O virus These characters may be maintained for several passages if carried out with limiting dilutions

3. O and ω̄ strains do not multiply readily in the allantoic cavity, whereas D and δ strains proliferate However, large doses of O virus will infect by the allantoic route (Burnet and Stone, 1945 *a*)

4 *O strains do not infect mice readily, but are highly infective for ferrets,* guinea-pigs, and man. Large inocula of O virus may initiate infection irregularly in mice (Burnet and Stone, 1945 *a*) D virus is not as active as O on intranasal inoculation in guinea-pigs

5 Human tears effectively inhibit [illegible] D strains, but fail to inhibit [illegible] ion by the D phase is

6. Slight ant [illegible] between the 2 phases, using ferret antisera

7 O and D viruses can be absorbed out of suspension, to a certain degree, by red cells that they agglutinate Absorption with fowl cells will not remove pure O virus from suspensions of infected embryo lung, but removes particles other than those in this phase (Burnet and Stone, 1945 *b*).

8 Certain B strains isolated by Hirst (1947 *b*) in 1945–6 had no tendency to the agglutination picture of O phase, but showed poor adaptation to mice and the allantoic cavity.

Maintenance of Virus in O Phase

Burnet and Stone (1945 *b*) outlined the following precautions to be observed in maintaining virus in the O phase during egg passage The inoculum should be prepared from embryo lung, rather than amniotic fluid, by absorption with fowl cells The fowl cells remove virus particles other than those in the O phase The

initial emulsion should show a F/G ratio of 1/10 or less, while the absorbed fluid should not agglutinate fowl cells. Dilutions are then prepared in horse serum saline, 10^{-4} to 10^{-6}, and inoculated amniotically in 13–14 day embryos It is essential to passage at limiting dilutions, for if more concentrated preparations are used, D phase virus will appear The lungs are harvested after not more than 72 hours at 35° C. O virus can be preserved in glycerolated amniotic fluid (Burnet, McCrea, and Stone, 1946).

Significance of the O-D Change

Human influenza virus A in its O phase is genetically unstable, and D phase, which is more stable, appears whenever virus has an opportunity to multiply sufficiently to provide an adequate number of replicas. In mouse and chick embryos the D type virus usually multiplies more freely and overgrows O, which requires special conditions for proliferation It is well known that as a rule 1 or 2 ferret passages are necessary before a newly isolated strain, i e, in the O phase, can be adapted to mice, i e, assume the D phase. The O form must have some specific character favoring its survival under epidemic conditions (Burnet and Bull, 1943)

O No agglutination	F/G ratio 0/40–0/1,000
ω Weak loose, rapidly disappears	1/20–1/3
δ Streaky or insular	1/3–1
D Continuous shield	1 or +

The agglutination reactions with red cells from various species are as follows:

	O	D
Fowl	not readily	readily
Guinea-pig	equally well agglutinated	
Human	equally well agglutinated	
Pigeon	equally well agglutinated	
Ferret	very weakly agglutinated	
Mouse	very weak	readily

It must be noted that normal amniotic fluid after the 13th day contains pseudoglobulin from the albumen sac, and this can cause agglutination of guinea-pig and many other cells, but not above a titer of 32; chick cells are not agglutinated (Commission, 1946 *b*).

2. When O phase virus is inoculated in the amniotic cavity, the amount of fluid is found to be increased, but this increase does not occur with D phase, where, in fact, the volume may be reduced Multiplication of O virus is more rapid in 13–14 than 12-day embryos. O virus does not usually kill the embryo in small doses within 4 days, fully adapted D strains usually kill in 2–3 days (Beveridge and Burnet, 1946).

After inoculation of O virus in the amniotic cavity, it can be recovered in this phase for the first 2–3 days, but thereafter intermediate D type virus is usually recovered. After the 5th day, no typical O virus is recoverable. As a general rule, virus is recovered in the same phase in both lung and amniotic fluid

If concentrated preparations are inoculated amniotically, D phase virus results, whereas if dilute inocula are used, the amniotic fluid may give the reactions characteristic of O virus. These characters may be maintained for several passages if carried out with limiting dilutions

3 O and ω strains do not multiply readily in the allantoic cavity, whereas D and δ strains proliferate. However, large doses of O virus will infect by the allantoic route (Burnet and Stone, 1945 *a*).

4 O strains do not infect mice readily, but are highly infective for ferrets, guinea-pigs, and man Large inocula of O virus may initiate infection irregularly in mice (Burnet and Stone, 1945 *a*) D virus is not as active as O on intranasal inoculation in guinea-pigs

5 Human tears effectively inhibit [illegible] strains, but fail to inhit [illegible] ion by the D phase is [illegible]

6 Slight ant [illegible] between the 2 phases, using ferret antisera

7 O and D viruses can be absorbed out of suspension, to a certain degree, by red cells that they agglutinate Absorption with fowl cells will not remove pure O virus from suspensions of infected embryo lung, but removes particles other than those in this phase (Burnet and Stone, 1945 *b*).

8 Certain B strains isolated by Hirst (1947 *b*) in 1945–6 had no tendency to the agglutination picture of O phase, but showed poor adaptation to mice and the allantoic cavity

Maintenance of Virus in O Phase

Burnet and Stone (1945 *b*) outlined the following precautions to be observed in maintaining virus in the O phase during egg passage The inoculum should be prepared from embryo lung, rather than amniotic fluid, by absorption with fowl cells The fowl cells remove virus particles other than those in the O phase The

Virus B has also been proved infective for human volunteers, the symptoms being in general similar to those recorded after inhalation of virus A, although perhaps somewhat milder, and the illness having a shorter incubation period, nausea and vomiting is not uncommon (Bull and Burnet, 1943, Burnet, 1943 *b*, Francis *et al*, 1944 *b*; Salk *et al*, 1945 *a*, Henle *et al*, 1946 *a*).

Local symptoms of sneezing and "stuffy" noses were commonly found in Bull and Burnet's series

Virus can be recovered from the nasal secretion of persons experimentally infected with virus B 48 hours later (Bull and Burnet, 1943)

By no means all persons exposed to atomized virus develop influenza, and the outcome of an experimental exposure may be considered to depend on various factors (Henle *et al*, 1946 *a*)· (1) the extent of multiplication of and invasion by the virus, (2) any toxic, as opposed to invasive, properties of the virus, (3) the presence of an allergic state due to previous "sensitizing" exposure; (4) to which may be added the state of immunity of the volunteer as evidenced by the level of antibody in the serum, or nasal secretions. Probably also some local susceptibility or resistance of the respiratory mucosa plays a part.

ANIMAL EXPERIMENTS

Influenza virus is capable of infecting a wide range of animal hosts, and in so far as the respiratory system is predominantly involved, it may be designated a "pneumotropic" virus (Waldmann, 1935).

Ferret

It was by means of the ferret that virus A was originally isolated by Smith, Andrewes, and Laidlaw (1933), and ferrets have been used extensively in later work. They are susceptible also to infection with swine strains B strains are adapted only with difficulty, if at all Certain precautions are necessary in work with ferrets, thus, they must be carefully quarantined for at least 14 days before use, as they may suffer from distemper (see Pyle, 1940).

It has been shown that ferrets may suffer from another epizootic of high fatality rate (Slanetz and Smetana, 1937, Slanetz, Smetana, and Dochez, 1936). This disease is due to a filtrable virus, and hemolytic streptococci may act as secondary invaders Spooner (1938) studied a somewhat similar disease that affected ferrets supplied in the London area in 1934–5 It presented much similarity to ferret distemper and to Slanetz and Smetana's disease Francis and Magill (1938 *b*) isolated a hitherto undescribed virus by ferret inoculation (virus of acute meningopneumonitis, see Ch LXVIII) Ferrets infected with influenza are highly infective, and readily infect others, unless rigid isolation is carried out

Method of inoculation Ferrets are usually susceptible only to intranasal instillation, administration by the intramuscular or subcutaneous routes does not cause infection. Direct intrapulmonary injection secures infection, but is not used in practice (Andrewes, Laidlaw, and Smith, 1934) The usual method of infecting ferrets is to drop about 0 5 c.c –1 5 c c. of inoculum on the nares of the animal, when held vertically Etherization may be carried out, and induces a severer infection, intraperitoneal nembutal can be used After intranasal inoculation, virus can be demon-

and Scott, 1944 *b*). They can become infected one from another over a distance of about 5 feet, probably by fine droplets, the interposition of a screen or increased ventilation prevents such cross infection (Andrewes and Glover, 1941).

Combined bacterial and virus infection. Glover (1941 *b*) found that a hemolytic

CHAPTER LVII

INFECTIVITY OF INFLUENZA VIRUS FOR MAN AND ANIMALS

HUMAN TRANSMISSION

EARLY in the course of influenza research, certain workers in London and New York developed influenza while attending to infected ferrets. The best-known case of this type is that recorded by Smith and Stuart-Harris (1936)[1] Stuart-Harris himself became infected after examining a batch of ferrets infected with passage virus, one of which sneezed in his vicinity. The whole circumstances of his attack were such as very strongly to suggest that he had become infected from this animal. The matter was finally settled when it was found that the virus isolated from Stuart-Harris possessed the properties of passage virus (actually the 196th passage), and not of fresh virus. This important observation showed that despite almost 200 passages through ferrets, the virus retained its pathogenicity for man It formed a very strong link in the chain of evidence incriminating the filtrable virus as the cause of influenza.

Further evidence for the infectivity of the virus for man was furnished by Soviet workers, Smorodintseff *et al.* (1937) inoculated volunteers with the WS (original London strain) and Leningrad strains of virus by spray. In a percentage of cases the patients developed symptoms of a mild attack of influenza.

Of more recent years, a number of experiments has established beyond doubt the pathogenicity of influenza viruses A and B for the human subject.

As regards the route of inoculation, it is generally agreed that it is not easy to infect human volunteers by simple instillation of drops of virus-containing fluid. Despite failure to cause symptoms, virus may persist in the nose, and be recovered after 72 hours (Henle *et al*, 1946 *a*).

Volunteers can, however, be infected readily by inhalation of an atomized suspension, the virus "mist" can be administered in an inhaling apparatus or in a small experimental chamber It appears that the virus must, therefore, enter the tissues by the lower, as opposed to the upper, respiratory tract

In this type of work it is necessary to fix a criterion of what is to be regarded as a positive result It appears that a temperature rise to 100° F. (oral) and over may be accepted as evidence of infection

With influenza A strains a number of workers has secured infection by inhalation (Burnet and Foley, 1940, Burnet, 1942 *b*, 1943 *b*, Henle, Henle, and Stokes, 1943, *Francis et al*, 1944 *a*, 1945, *U S Nav Med Lab*, 1944 *b*, *Henle et al*, 1946 *a*)

For example, Henle *et al* (1946 *a*) found febrile responses in 58/65 persons after inhalation of 0 4 to 0 8 c c of finely atomized pure allantoic fluid Fluid diluted 10^{-1} or 10^{-2} was usually noninfective

The reaction to inhalation of virus A usually comes on within 24 hours, but may be delayed for 36 hours or more The fever seldom lasts for more than 48 hours. Common symptoms and signs are malaise, chills, headache, generalized aching and pains, flushing of the face, cough, and leukopenia Local coryzal symptoms may occur. Antibody rise occurs after experimental infection (see Ch LXIII) Subclinical infections may also occur, being shown by slight rises of temperature, leukopenia, or a rise in antibody

Virus can be recovered from throat washings after inhalation, for example by amniotic inoculation (see, e g, Burnet and Foley, 1940, Henle, Henle, and Stokes, 1943).

[1] References are appended at the conclusion of Ch LXIII, p 671 et seq

they found that the epithelium was resistant to influenza virus, to iontophoresis, and to zinc sulfate Later, resistance to virus remained, but the other agents acted as if in normal animals, although some degree of resistance to zinc sulfate remained for 5 weeks. They considered that this resistant state is nonspecific, but of temporary importance in immunity.

The upper part of the trachea appears normal, but there is a polymorph infiltration in the lower portion (Perrin and Oliphant)

In early passages, the lungs show reddish-purple patches, but with further passages become definitely consolidated According to Perrin and Oliphant, by the first day there is early bronchitis, pulmonary congestion, and infiltration of inflammatory cells. By the 2nd and 3rd days the bronchitis is purulent, with some degeneration of the epithelium. The alveolar exudate contains polymorphs and large mononuclears There is some perivascular cuffing. The pneumonic lesions are most pronounced in the bases of the lower lobes. The pneumonia progresses till the 6th day. After the 7th day there is evidence of proliferative change replacing the exudate, and this progresses so that by the 14th day the pneumonic areas are definitely smaller.

According to Sheftel (1940), after intranasal inoculation, encephalitis or meningoencephalitis may ensue.

Adsorption of influenza virus on cells of the respiratory tract The adsorption of influenza virus by red cells is probably due to specific receptors on the adsorbing cells (see Ch. LXI), and it is probable that the cells of the respiratory system possess similar receptors.

Hirst (1943 *a*) has investigated the problem by injecting allantoic fluid into the trachea of perfused and excised ferret lungs. Virus titers were studied by the chick cell agglutination (CCA) test and mouse infectivity. (1) Using PR8, almost all the virus was removed from the perfusing fluid in 5 minutes Elution was noted after 2 hours, and by 5 hours about 25 per cent of the amount adsorbed had been eluted In the case of the Lee strain, the release of virus was 75 per cent. complete in 5 hours. (2) After elution of virus, the cells did not appear capable of adsorb-

When examining ferrets 24 hours after inoculation, however, free agglutinin was readily detected, probably due to multiplication of virus after destruction of available receptors Hirst postulates that the destruction of a specific receptor substance may be a preliminary to parasitization of the susceptible cell by influenza virus This may involve an enzymatic reaction

Mouse

That mice could be infected was first shown by Andrewes, Laidlaw, and Smith

mice which, when passaged, produces extensive respiratory involvement (see also Gordon *et al*, 1938) Freeman (1940) has drawn attention to a spontaneous pneumonitis of mice which has some resemblance to influenzal infection It is distinguishable histologically by the absence of bronchiolar metaplasia and the presence of hepatitis

Mice are susceptible to infection with A, B, and swine strains of virus Friedewald and Pickels (1944), on the basis of centrifugation studies, concluded that approximately 10 infective particles are needed to infect mice with PR8, but 10,000

streptococcus (Group C) was transmissible in ferrets along with the virus, the double infection being more severe than that due to the virus alone. When streptococci were inoculated in animals previously exposed to virus, infection was caused

Course of the disease. The course of the experimental disease depends on the number of passages the virus has undergone, and whether the animal is etherized at the time of inoculation. As already mentioned, strains of virus recovered in the absence of severe epidemics are often difficult to pass to ferrets (see p. 583). When inoculated (without any etherization) with comparatively unpassaged strains, animals become ill after about 2 days The temperature rises to 105°–106° F. (normal 102° F.), and then falls; a characteristic feature is the appearance of a second "spike" of high temperature 2–3 days later, but this diphasic response may not be observed The animal is obviously ill, being quiet and weak It soon shows evidence of catarrh of the nose and eyes, and there is a purulent obstruction of the nasal passages with some discharge. Sneezing is a common feature and serves to disseminate the infection. The animal usually recovers in 7–10 days The addition of *Hemophilus influenzae suis* to the inoculum of virus does not render the attack any more severe (Smith, Andrewes, and Laidlaw, 1933).

When the animals are thus inoculated, the reaction appears to be localized to the upper part of the respiratory tract. Actually, however, virus may be present in [illegible] nd after 3 to 4 "passages-by-faith" [illegible] usually develops (Francis, 1935). The virus strain frequently requires a few passages before it begins to produce pneumonia regularly on the 4th to 5th day. Pneumonic animals suffer from a more severe illness than those presenting only catarrh, the breathing being labored and rapid. A similar pneumonic process develops when virus which has been frequently passaged is injected without ether (see Laidlaw, 1935).

Technique of passage. It is best to kill the ferret while still showing symptoms The turbinates are removed, ground with sterile abrasive, and a saline suspension is then centrifuged. A Gradocol membrane filtrate is prepared from the supernatant, for passage. If desired, lung suspensions can be similarly prepared

Pathology. The pathology has been studied by a number of authors (e g, by *Smith, Andrewes, and Laidlaw, 1933; Brightman, 1936;* McIntosh and Selbie, 1937 *a*, *b*, Perrin and Oliphant, 1940).

The nose is full of purulent exudate and the nasal mucosa is swollen and inflamed Microscopic examinations have been reported fully by Francis and Stuart-Harris (1938 *a*) and Perrin and Oliphant [illegible] Perrin and Oliphant, who worked with the PR8 strain, after 2 [illegible] congested and shows focal infiltration [illegible] lymphocytes. By the end of 48 hours, these changes are more marked and polymorphs are more numerous Over the turbinates, the *columnar ciliated epithelium* is replaced by a single layer of flat cells with small areas of denudation. By the 3rd or 4th day, both respiratory and olfactory mucosae are involved Changes vary from ferret to ferret, but usually not more than half the available area is involved

The process of repair begins by the 5th to 6th day, when there is definite *stratification of the polyhedral epithelial cells* of the respiratory mucosa By the 7th to 11th days, cellular infiltration is less, and most of the respiratory mucosa is covered by stratified transitional epithelium By the 19th day, most of the respiratory epithelium covering the turbinates and floor is stratified *columnar, while that* on the roof and walls is normal (Perrin and Oliphant)

If repeated inoculations are given, the mucosa shows a marked acceleration of repair (Francis and Stuart-Harris, 1938 *b*)

The epithelial changes that occur in the mucosa during recovery from infection were *found to* be associated with a functional alteration in the susceptibility to various substances (Stuart-Harris and Francis, 1938). On the 7th to 8th days,

they found that the epithelium was resistant to influenza virus, to iontophoresis, and to zinc sulfate Later, resistance to virus remained, but the other agents acted as if in normal animals, although some degree of resistance to zinc sulfate remained for 5 weeks They considered that this resistant state is nonspecific, but of temporary importance in immunity.

The upper part of the trachea appears normal, but there is a polymorph infiltration in the lower portion (Perrin and Oliphant)

In early passages, the lungs show reddish-purple patches, but with further passages become definitely consolidated. According to Perrin and Oliphant, by the first day there is early bronchitis, pulmonary congestion, and infiltration of inflammatory cells By the 2nd and 3rd days the bronchitis is purulent, with some degeneration of the epithelium The alveolar exudate contains polymorphs and large mononuclears. There is some perivascular cuffing. The pneumonic lesions are most pronounced in the bases of the lower lobes. The pneumonia progresses till the 6th day After the 7th day there is evidence of proliferative change replacing the exudate, and this progresses so that by the 14th day the pneumonic areas are definitely smaller.

According to Sheftel (1940), after intranasal inoculation, encephalitis or meningoencephalitis may ensue.

Adsorption of influenza virus on cells of the respiratory tract The adsorption of influenza virus by red cells is probably due to specific receptors on the adsorbing cells (see Ch LXI), and it is probable that the cells of the respiratory system possess similar receptors

2 hours, and by 5 hours about 25 per cent of the amount adsorbed had been eluted. In the case of the Lee strain, the release of virus was 75 per cent. complete in 5 hours. (2) After elution of virus, the cells did not appear capable of adsorbing any more (3) Heat- or formalin-inactivated virus was adsorbed but not eluted

Hirst (1943 *a*) also carried out experiments on the intranasal inoculation of living ferrets The animals were killed at varying periods after inoculation, and the lungs perfused and excised Buffer injected into the trachea was then tested for the CCA titer The virus was rapidly adsorbed, and after a period could not be eluted. When examining ferrets 24 hours after inoculation, however, free agglutinin was readily detected, probably due to multiplication of virus after destruction of available receptors Hirst postulates that the destruction of a specific receptor substance may be a preliminary to parasitization of the susceptible cell by influenza virus This may involve an enzymatic reaction

Mouse

That mice could be infected was first shown by Andrewes, Laidlaw, and Smith

mice which, when passaged, produces extensive respiratory involvement (see also Gordon *et al*, 1938) Freeman (1940) has drawn attention to a spontaneous pneumonitis of mice which has some resemblance to influenzal infection It is distinguishable histologically by the absence of bronchiolar metaplasia and the presence of hepatitis.

Mice are susceptible to infection with A, B, and swine strains of virus. Friedewald and Pickels (1944), on the basis of centrifugation studies, concluded that approximately 10 infective particles are needed to infect mice with PR8, but 10,000

with Lee (B). Himmelweit (1943) could not infect mice with the Paddington strain of virus B, and other strains have also proved noninfective.

Intranasal instillation. Mice are generally inoculated by dropping 0·05 c.c. of inoculum into the nares under light etherization. As a general rule mice can be infected only with ferret- or egg-passaged material, human washings usually failing to infect (Andrewes, Laidlaw, and Smith, 1935; and see p. 584). Certain strains, unusually virulent for the mouse, have, however, been isolated directly from washings; it is usually necessary to pass the lungs "blind" for a few times before lesions are found (Clampit and Gordon, 1937, Francis and Magill, 1937 *b*, Francis *et al*, 1937 *a*; and see p. 585). When lung suspensions are passed every 24–48 hours, there is a danger of bacterial pneumonia developing, probably due to the animal's nasal flora being washed into the lungs, this can be obviated by adding penicillin and streptomycin to the lung suspensions (McKee and Hale, 1947).

Following nasal instillation, virus rapidly invades the lung, and may also be isolated from blood, urine, bile, spleen, liver, and brain (Cerrutti, 1937; Smorodintseff and Ostrovskaya, 1937; Burnet and Lush, 1938 *b*; Bijl and van Genderen, 1939); it has also been detected in the mediastinal lymph glands (Burnet and Lush, 1938 *b*), and feces after 3 days (Sarracino and Soule, 1941 *b*). After intranasal inoculation, there is a large increase in virus in the lung within 20 hours, with a peak at 48 hours, little consolidation is present at this stage, but is well marked after 72 hours (Burnet and Lush, 1938 *b*). Taylor (1941 *c*) found that following the intranasal instillation of PR8, there is a rapid increase of virus in the lungs, and with large doses this becomes maximal within 24 hours; with smaller inocula the maximum concentration may not be reached till 48 hours after inoculation He made the interesting observation that even if a sublethal dose of virus is inoculated, the lungs may contain at least 78,000 MLD of virus, the mouse, however, survives

Following intranasal instillation of virus, death may ensue from pneumonia in from 3–7 days With weaker inocula, or less active viruses, the animal may survive and show varying degrees of pulmonary consolidation. Finally, if a sublethal dose is given, the animal remains apparently healthy.

An interesting phenomenon may be observed following intranasal inoculation. If a sublethal dose of virus is administered, and a second instillation of sterile water, Tyrode, saline, broth, or 10 per cent. normal serum is given after 4 days, there is a sharp rise in the virus content of the lung, and the animal dies in 3–8 days (Straub, 1940, Taylor, 1941 *c*) This effect can be produced if the 2nd injection is given up to 10 days after the first, but not if the second injection is of immune serum. Taylor suggests that the second inoculation "releases" virus already present in the cells of the respiratory mucosa to spread by the air passages and give rise to a true virus pneumonia These observations were confirmed by Harford, Smith, and Wood (1946).

The process of adaptation to mouse lung has been recently re-explored by Hirst, (1947 *a*) who suggests that it is commonly assumed that on initial transfer in a new host, a virus grows poorly, and only a few particles survive These survivors are held to be variants with greater capacity for multiplication in the new host Serial passage favors the emergence of further variants. The process of adaptation of influenza virus to mouse lung that he reports may, however, require some other interpretation of the adaptive process to be advanced

1 This experiment concerned an influenza A strain that was isolated by amniotic inoculation, and subsequently went through 4 allantoic passages The allantoic fluid of the 5th egg passage was inoculated nasally in mice After 3 days the mice were killed and lung suspensions passed to further mice, and so on in series Each mouse lung preparation and the original allantoic fluid were titrated in the egg and in mice Although the initial inoculum contained large numbers of egg infectious particles, it caused no deaths in mice However, the apparently normal lungs of these mice contained large amounts of virus as shown by egg-infectivity

tests, mouse lungs of the first passage contained as much virus as did those of subsequent passages By about the 6th passage in mice, lung suspensions were killing mice in high dilutions, and this level was maintained without further increase through many subsequent generations. In general, the titer of lung suspensions for eggs remained constant throughout the process of adaptation, and showed no marked tendency to increase.

2. In work with another strain of A virus, an attempt was made to correlate the hemagglutinin titer in the lungs with the titer in eggs Two trends were noted the agglutinin titer against chick cells did not increase with passage, but the titer against guinea-pig cells did, further, the guinea-pig chicken cell titer ratio was 1, but during passage was usually over 1, and increased to 128. It appeared as if the original D phase virus was becoming, on passage, more like Burnet's O form

Summarizing this interesting work, it has been shown that the enhancement of virulence for the mouse lung with mouse lung passage is not due to an increasing ability of the virus to grow in the lung. Rather, the egg-infecting type of virus seems to be gradually replaced by an entity having the same egg growth potentialities but t

Cage

as infectc

fatal, WS and PR8 strains were found to give rise to contact infection more readily than Melbourne or swine strains (Eaton, 1940 *b*). This type of infection may arise by inhalation of droplets, or by ingestion, as lung lesions may follow the introduction of virus by this route (Eaton)

Infection by inhalation Numerous workers have shown that mice can be infected by exposure to finely atomized virus suspensions (A or B) in a small closed b

i(

F

i(

a

die. Animals are highly susceptible to infection by inhalation, and the course of the disease depends on the amount of virus inhaled Thus even 15 seconds exposure to as little as 0 2 to 0 3 c c of virus suspension diluted 10^{-2} dispersed in a chamber of 60 liters capacity was sufficient to produce pulmonary lesions in all animals; death regularly followed exposure for 2 minutes (Loosli, Robertson, and Puck, 1943) In these experiments, the infective droplets were calculated to measure 2–3 μ Knight (1946 *a*) infected mice in parallel by instillation and exposure to a spray. He found that the virus content of the lung, as measured by the agglutinating activity for chick cells, was usually about 50 per cent. higher in the animals infected by inhalation

Intracerebral injection The ordinary WS strain is not encephalitogenic (Daddi and Panà, 1938) Stuart-Harris (1939) has produced a variant of this strain by egg passage which gives rise to encephalitis in mice, and can be passed by the intra cerebral route Francis and Moore (1940) confirmed these observations, but found it unnecessary to pass the strain through eggs, they used a tissue culture as the source of virus They found that the Melbourne strain produced similar changes, but not swine or several other strains

Neurological signs ascribed to toxic properties in the influenza virus have been observed by certain workers (see below).

Injection by other routes Mice can be infected by direct injection into the lungs, through the chest wall (Andrewes, Laidlaw, and Smith, 1934).

Following intraperitoneal or intravenous inoculation of large doses, virus can be recovered from the lungs, after subcutaneous inoculation, virus can be detected in the regional lymph glands (Rickard and Francis, 1938, Henle and Henle, 1946 *b*).

with Lee (B). Himmelweit (1943) could not infect mice with the Paddington strain of virus B, and other strains have also proved noninfective.

Intranasal instillation. Mice are generally inoculated by dropping 0.05 c.c. of inoculum into the nares under light etherization. As a general rule mice can be infected only with ferret- or egg-passaged material, human washings usually failing to infect (Andrewes, Laidlaw, and Smith, 1935, and see p. 584). Certain strains, unusually virulent for the mouse, have, however, been isolated directly from washings; it is usually necessary to pass the lungs "blind" for a few times before lesions are found (Clampit and Gordon, 1937, Francis and Magill, 1937 *b*, Francis *et al*, 1937 *a*; and see p. 585). When lung suspensions are passed every 24–48 hours, there is a danger of bacterial pneumonia developing, probably due to the animal's nasal flora being washed into the lungs, *this can be obviated by adding penicillin and* streptomycin to the lung suspensions (McKee and Hale, 1947).

Following nasal instillation, virus rapidly invades the lung, and may also be isolated from blood, urine, bile, spleen, liver, and brain (Cerrutti, 1937, Smorodintseff and Ostrovskaya, 1937; Burnet and Lush, 1938 *b*, Bijl and van Genderen, 1939), it has also been detected in the mediastinal lymph glands (Burnet and Lush, 1938 *b*), and feces after 3 days (Sarracino and Soule, 1941 *b*). After intranasal inoculation, there is a large increase in virus in the lung within 20 hours, with a peak at 48 hours; little consolidation is present at this stage, but is well marked after 72 hours (Burnet and Lush, 1938 *b*) Taylor (1941 *c*) found that following the intranasal instillation of PR8, there is a rapid increase of virus in the lungs, and with large doses this becomes maximal within 24 hours; with smaller inocula the maximum concentration may not be reached till 48 hours after inoculation He made the interesting observation that even if a sublethal dose of virus is inoculated, the lungs may contain at least 78,000 MLD of virus, the mouse, however, survives

Following intranasal instillation of virus, death may ensue from pneumonia in from 3–7 days With weaker inocula, or less active viruses, the animal may survive and show varying degrees of pulmonary consolidation. Finally, if a sublethal dose is given, the animal remains apparently healthy

An interesting phenomenon may be observed following intranasal inoculation If a sublethal dose of virus is administered, and a second instillation of sterile water, Tyrode, saline, broth, or 10 per cent. normal serum is given after 4 days, there is a sharp rise in the virus content of the lung, and the animal dies in 3–8 days (Straub, 1940, Taylor, 1941 *c*). This effect can be produced if the 2nd injection is given *up to 10 days after the first, but not if the second injection is of immune serum* Taylor suggests that the second inoculation "releases" virus already present in the cells of the respiratory mucosa to spread by the air passages and give rise to a true virus pneumonia These observations were confirmed by Harford, Smith, and Wood (1946)

The process of adaptation to mouse lung has been recently re-explored by Hirst, (1947 *a*) who suggests that it is commonly assumed that on initial transfer in a new host, a virus grows poorly, and only a few particles survive These survivors are held to be variants with greater capacity for multiplication in the new host Serial passage favors the emergence of further variants The process of adaptation *of influenza virus to mouse lung that he reports may, however, require some* other interpretation of the adaptive process to be advanced

1. This experiment concerned an influenza A strain that was isolated by amniotic inoculation, and subsequently went through 4 allantoic passages The allantoic fluid of the 5th egg passage was inoculated nasally in mice. After 3 days the mice were killed *and lung suspensions passed to further mice*, and so on in series Each mouse lung preparation and the original allantoic fluid were titrated in the egg and in mice Although the initial inoculum contained large numbers of egg infectious particles, it caused no deaths in mice However, the apparently normal lungs of these mice contained large amounts of virus as shown by egg-infectivity

pear dilated. There is edema of the peribronchial tissue with slight monocytic infiltration The first result of the dilatation of the respiratory bronchioles is to give emphysema. Later, the alveoli become collapsed, and edema and congestion give rise to areas of consolidation. Collapse is a complication only, and not a specific change; it may be absent in adult mice or those infected with a weak virus.

Straub describes the reparative lesions beginning about the 5th day, when the larger bronchi return to normal, in the bronchioles the epithelium proliferates and becomes almost stratified (see also Laidlaw *et al*, 1935). This overgrowth fills the terminal air spaces, so that eventually the involved area becomes functionless.

Straub's findings with virus A have been confirmed by de Balogh (1939) and others (Nelson and Oliphant, 1939, Hoyle and Orr, 1945; Harford, Smith, and Wood, 1946). de Balogh reports necrosis and desquamation of alveolar epithelium, and evidence of motor dysfunction of the muscular tissue of the bronchioles, pulmonary arteries and arterioles, due to lesions in the ganglion cells of the bronchial wall.

Nelson and Oliphant infected mice by the intranasal instillation of PR8 virus and examined the lungs at frequent intervals. Signs of bronchial epithelial damage and bronchitis were noted even after 24 hours. Epithelial damage was more marked after 48 hours, when the early polymorph exudate in the bronchi was necrotic. There was perivascular edema and peribronchial and perivascular infiltration with small mononuclears After 3–4 days they found a diffuse edema, and a septal and alveolar infiltration with polymorphs and mononuclears Some bronchial epithelium was denuded Animals surviving for 6 days lived indefinitely and showed squamous metaplasia in the alveoli

Hoyle and Orr studied the changes from day to day after intranasal instillation of WS They found slight desquamation and inflammation of the bronchial epithelium after 24 hours. After 48 hours there was well-marked epithelial degeneration, with plugs of mucopus in the lumina, focal bronchiolar dilatation, and peribronchitis. After 72 hours there was focal denudation of the bronchial wall After 4–6 days, regeneration of the bronchial epithelium was seen, with stratification They concluded that the alveolar changes resembled those seen in bacterial infections.

The histopathology of infection with virus B has been reported by Oliphant and Perrin (1942), who found that the changes are essentially as seen with virus A. There are degenerative changes in the bronchi, followed by reparative proliferation In the late stages there is plugging of the alveoli by epithelial cells of squamous type

The histological features after the intranasal inoculation of swine virus are fully described by Dubin (1945), who likens them to those due to human strains He found necrotic changes in the bronchial and alveolar lining, often with formation of a hyaline membrane The bronchial changes give rise to collapse. Proliferative repair in the bronchi and bronchioles is very marked, and cells invade and fill the alveoli. About the 14th day many alveolar plugs degenerate and reopen the alveoli. The epithelium of the bronchi and bronchioles is restored to normal in the 3rd week There is, in addition to the bronchitis, a pneumonia characterized by hyaline necrosis of alveolar cells, congestion and focal hemorrhage, edema, and interstitial infiltration with mononuclears

Sheftel (1940) has described the presence of encephalitis and meningo-encephalitis after intranasal infection.

Influenza virus appears to have a somewhat inhibitory effect on the development of primary lung tumors occurring in mice after exposure to dust (Campbell, 1940)

An interference phenomenon The cerebral inoculation of large doses of WS virus mixed with western equine virus interferes with the proliferation of the western virus PR8 and Lee also interfere (Vilches and Hirst, 1947).

Technique of autopsy on mice. When it is necessary to examine the lungs of large numbers of mice, as in titration experiments, and particularly when they are to be removed with aseptic preparations, the technique of Himmelweit (1944) can be recommended: the mouse is pinned to a board on its back. The skin over the lower abdomen is picked up with forceps and "nicked" with scissors. The skin can then be torn upwards and laterally by traction with the forceps, exposing the abdomen, thorax, and root of the neck. This flap is then pinned down. These nonsterile instruments can be used for a whole series of mice. The exposed thoracic wall can be regarded as sterile, and is then opened with a second (sterilized) pair of instruments, and the lungs removed.

When examining lungs for pneumonic lesions, it is important to remove the organs from the thorax, as the heart covers most of the lung surface *in situ*. Alternatively the thorax can be opened from the back.

Influence of physical and chemical agents on infection. Mice kept at 95° F., after intranasal instillation of PR8, showed lesser degrees of pulmonary consolidation than those kept in a cold room (Sulkin, 1945).

Alcohol, heat, cold, and fatigue did not render animals more susceptible to infection (Sarracino and Soule, 1941 *a*).

The intraperitoneal administration of atropine sulfate shortly before the nasal instillation of PR8 decreased the incidence and extent of infection, perhaps because of the consequent reduction in mucous secretion (Wheeler and Nungester, 1944).

Combined virus and bacterial infections. A number of authors has described the effects of subjecting mice to double infections with bacteria and organisms. Thus, Herzberg and Gross (1940) were able to pass a Type 3 pneumococcus and influenza virus serially in mice without loss of virulence of either component.

Experiments have been conducted by exposing mice to atomized bacteria after infection with virus A. For example, Wells and Henle (1941) administered Type 1 pneumococcus suspension 1–5 days after a fatal dose of virus, and found that death occurred more quickly with the double infection. When sublethal doses of virus were employed, there was an increased mortality rate and a greater incidence of severe lesions in those animals with the double infection. Similar observations have been made by Francis and de Torregrosa (1945) using *H. influenzae*, staphylococcus, and hemolytic streptococci; they found that these organisms invaded the lungs of mice only if superimposed on a preexistent virus infection. Harford, Smith, and Wood (1946) found that when mice showing reparative changes in their bronchial epithelium due to virus infection were exposed to atomized bacteria, there occurred polymorph infiltration and alveolar edema in addition to the virus changes.

Ballowitz (1944 *b*) infected mice with paratyphoid bacilli by the mouth, and then instilled virus nasally. He found that under these conditions general dissemination of the organisms was facilitated (see also 1944 *a*).

PR8 was found to enhance the development of lesions in the lungs due to infection with tubercle bacilli (Volkert *et al.*, 1947).

Pathology. The infection in the mouse is mainly localized in the lungs, whereas in the ferret the changes are chiefly in the upper respiratory tract. Naked-eye the lungs show varying degrees and extent of consolidation. Part of one lung only may be involved, or in severe infections both organs may be "solid." The affected areas are firm and purple, and depressed below the surface of the remaining emphysematous portions.

Although the histological features were studied by earlier workers, Straub (1937, 1939, 1940) using the WS strain has furnished one of the most complete accounts. He finds that influenza virus affects specifically the epithelium of the respiratory tract from the bronchioles to the bifurcation of the trachea. The primary change is necrobiosis and fibrinoid necrosis of the bronchiolar epithelium. The terminal and respiratory bronchioles are denuded of their epithelium and ap-

thickening due to proliferation of endothelial cells O phase virus is more virulent than D phase (see Ch LVI)

Woolpert *et al* (1938) have shown that the fetal guinea-pig can be infected cerebrally with the PR8 strain of virus The virus could be recovered from the fetal lung, liver, blood, and brain as well as from the placenta (see also Dettwiler, Hudson, and Woolpert, 1940).

Hedgehog. Stuart-Harris (1936) found that a mild, but contagious respiratory infection could be produced in hedgehogs, and he was able to pass the infection in series The animal should be inoculated intranasally.

Rabbit. Intranasal inoculation gives rise to an inapparent infection (Hyde, 1942), McIntosh and Selbie (1937 *a*, *b*) recorded the presence of lung lesions resembling those of guinea-pigs Cerruti and di Aichelburg (1937) found that the virus survives subclinically in the brain after intracranial injection, while Daddi and Panà (1937) found evidence of inflammatory reaction.

Monkey. Intranasal inoculation may produce mild signs of infection (Vieuchange, 1939), direct intratracheal injection in cynomolgus monkeys may produce a fatal virus pneumonia characterized by bronchiolitis and interstitial changes (Burnet, 1941 *b*) Extensive experiments with *M. mulatta* have been carried out by a group of investigators (Merino *et al*, 1941, Woolpert *et al*, 1941, Saslaw *et al*, 1946, Wilson *et al*, 1947) with the following conclusions

1. Nasal inoculation in normal animals may produce a subclinical infection characterized by leukopenia A much more severe and usually fatal infection with lung changes occurs in nutritionally deficient animals, or animals exposed to cold

2 Intratracheal injection may produce signs of infection and leukopenia, severe in nutritionally deficient animals.

3. Simultaneous nasal inoculation of normal animals with virus and streptococci failed to produce evident disease Most of the animals showed a virus-induced leukopenia preceded by a leukocytosis due to the streptococci

4 Inoculation of streptococci 4–17 days after the virus produced disease in some animals, and a few developed fatal streptococcal septicemia.

5 A number of monkeys inoculated with both agents developed glomerular nephritis

6 Reinoculation with streptococci caused a rise in opsonins, precipitins, and antistreptolysin titers Administration of virus prevented this effect

7. It was concluded that virus infection predisposed to secondary bacterial invasion, and depressed the cellular and humoral defense mechanisms

[illegible] embryo chick it is surprising that [illegible] before show no pathological cha[illegible] hatching is the factor determining resistance (Enders and Pearson, 1941)

Chinese mink Tang (1938) found that *Mustela sibirica* (Milne-Edwards) is susceptible to the WS strain, after intranasal inoculation a febrile response develops. With passage, extensive pneumonic consolidation occurs

Miscellaneous The following have all been reported susceptible to influenza virus

1 David's squirrel—*Sciurotamias davidianus* (Milne-Edwards) (Tang, 1938).

2 Corean squirrel—*Eutamias asiaticus orientalis*, and

3 Manchurian squirrel—*Citellus mongolicus umbratus* (Thomas) (Tsurumi, Ogisawara, and Takagi, 1939)

4 Kangaroo rat—*Dipodomys* (Eaton, Martin, and Talbot, 1941)

5 *Galictis furax furonax* (Taylor, Parodi, and Chialvo, 1942–3)

6 A group of Tunisian rodents—*Gerbillus hirtipes, Dipodillus campestris, D. dodsoni*—are all said to be as susceptible as the mouse, *Meriones shawi* and *Jaculus jaculus* are less susceptible (Durand, 1945).

Pig

Human influenza strains, e.g., WS and PR8, can be transmitted to the pig by nasal instillation under light etherization (Elkeles, 1934; Shope and Francis, 1936, Tulloch, 1939, Mote and Fothergill, 1940). Shope and Francis concluded that the intranasal inoculation of human virus causes a mild illness with scanty lesions in the lungs, this illness is similar to that produced by the swine virus When *H. suis* and human virus are administered together, an illness resembling a mild attack of swine influenza develops, pneumonia is found, but is less severe than that of true swine influenza.

Certain evidence has been obtained which suggests that pigs may become infected naturally with human virus. Thus, Shope (1938) investigated the serum antibodies of pigs in American farms on which workers had suffered from epidemic influenza in 1936–7. Two classes of pig were examined, those that had lived through the 1936–7 epidemic, and those born subsequently. In the older pigs he found virus neutralizing antibodies to the human virus, while the young pigs' sera contained no antibodies to this virus. As these older animals were, and had always been, in perfect health, he suggested that they had acquired a subclinical infection with a human virus (see similar observations of Shaw *et al.*, 1939).

Hamster

Various workers have reported on the susceptibility of Syrian hamsters to influenza virus, and their value in diagnostic work (see p 584).

The European hamster (*Cricetus cricetus*) can be infected with ferret-passed material by intranasal inoculation, but not with human material (Taylor and Dreguss, 1940 *a*).

The Chinese hamster was found to be susceptible to strains of virus A in early mouse passages, the incubation period is 3–6 days, and death occurs after 4–10 ... onsolidation (Yen, 1940).

... that virus A suspended in mucin injected ... the lungs, similar to those found in mice.

Other Animals

Rat Various workers have attempted to infect the rat by intranasal inoculation of human washings or passage virus (Agapov, 1936, Stuart-Harris, 1937 *b*, Valls Conforto, 1938, Hyde, 1942) After inoculation of washings, the animals do not show marked symptoms, but develop a subclinical illness, virus can be recovered from the nose and lung (Stuart-Harris) A fatal infection may follow the inoculation of ferret-passed material (Valls Conforto).

Harford *et al* (1946) have produced a mild infection in rats by direct intrabronchial inoculation with PR8 virus The animals were etherized and a cannula passed through the larynx under direct vision, and thence into the left main bronchus. A catheter was passed through this cannula into the lower part of the left lobe, so that the inoculum was consistently placed close to the lower pole Lesions occurred near the point of inoculation The area involved was dark red and firm Microscopically, there was edema and cellular infiltration of the peribronchial and perivascular tissue, and infiltration of cells into the walls and lumina of the alveoli Twenty-four hours after inoculation, most of the infiltrating cells were polymorphs, but after 4 days large mononuclears predominated There was no necrosis of epithelial cells—an unusual finding.

Guinea-pig Like the ... infection (Stuart-Harris, 1937 *b*, Bijl and ... may be recovered from the nose only, bu ... patches of collapse and hemorrhage in the lungs, the alveoli contained serous exudate, and there was

¼, +, ½, ++; ¾ consolidated, +++. Fifty per cent. end points are then calculated (Reed and Muench), 3 different criteria being employed, (*a*) death due to influenza within 10 days, (*b*) development of pulmonary consolidation within 10 days, (*c*) a weighted composite taking account of death and the extent of consolidation. It was found that the chances are 19/20 that differences of 0 99, 0 77 and 0 73 logarithmic units respectively for the lesion, the death, and the weighted end-points are significant.

Knight (1944 *b*) compared the accuracy of titration by inoculation of mice and chick embryos, in parallel. He found that accurate results can be obtained when 10 embryos or mice are used per dilution, but sufficient accuracy is achieved with 5. He found that the embryo is sensitive to considerably smaller amounts of virus than mice. (Titrations in eggs are fully described in Ch. LIX, and by red cell agglutination in Ch. LXI).

LABORATORY CONTAMINATION WITH INFLUENZA VIRUS

Andrewes *et al* (1944) described a number of incidents where accidental contamination with laboratory strains of influenza virus occurred during transmission experiments The contaminating virus may have gained entrance due to inadequate sterilization of instruments or glassware, or from dust.

7. Cane rats–*Zygodontomys microtinus stellae*, and
8. Bush rats–*Proechimys cayennensis o'connelli* (Allen) (Weir, 1944).

TOXIC EFFECTS OF VIRUS IN ANIMALS

It has been suggested that some strains of influenza virus may, under certain conditions, produce effects by virtue of a toxin rather than by reason of its invasive powers.

Thus neurological signs such as tonic and clonic convulsions, produced in mice by the intracerebral inoculation of concentrated preparations, have been ascribed to a toxin. These signs come on after 12–48 hours, and the animals die after 24–72 hours. Histologically, there is destruction of the ependyma of the ventricles. There *is no evidence of virus multiplication and passage cannot be performed (Henle* and Henle, 1944 *c*, 1946 *a*, Hale and McKee, 1945 *b*). The toxic effect can be abolished by ultraviolet rays, heat, or formalin, and neutralized by specific antiserum (Henle and Henle, 1944 *c*, 1946 *a*). Inoculation of virus A and B in the rabbit's eye produced corneal opacity, there was no multiplication of virus, and the effect was neutralized by type-specific serum (Evans and Rickard, 1945).

Toxic changes can also be shown in mice injected intravenously or intraperi- [illegible] in 18–46 hours with necrosis of the liver and spleen, [illegible] emorrhage in the gastro-intestinal tract, this effect [illegible] (Henle and Henle, 1945 *c*, 1946 *b*). Some die after 6–8 days with pulmonary consolidation; this effect is more pronounced with dilute preparations of virus; in some mice jaundice may develop (1946 *b*).

Henle and Henle (1946 *a*, *b*) have found that the toxic factor cannot be separated from the virus particle, and has the following properties· It is not dialyzable through cellophane, it is sedimented with the 600 S and not the 30 S component, it can be adsorbed to, and later eluted from, chick red cells, it can be precipitated *by protamine, it resists storage at 4° C. for 2–3 months; it withstands freezing* and thawing. Mice were immunized with allantoic fluid inactivated by UVL and rendered resistant to a challenge inoculation of the homologous toxic factor (*1946 b*).

In eggs, these workers found (*1946 b*) that the infective titer of virus in allantoic fluid often reached its peak within 24 hours, whereas maximum toxicity was not reached before the 2nd day. The application of heat, formalin, or irradiation with UVL caused more alteration in infectivity than in toxicity (see also 1947). There seems little doubt, however, that influenza virus has toxic properties, and that the virus particle itself carries the toxic property Toxicity and infectivity are possibly based on different constituents of the particle

TITRATION OF INFECTIVITY OF INFLUENZA VIRUS

It is often desired to assay the potency of virus preparations *in vivo*, and it is usual to carry out such infectivity tests by intranasal inoculation in mice A simple method is to make serial tenfold dilutions of virus, e g, of allantoic fluid in 10 per cent. serum-saline, and inoculate 0 05 c c of each dilution intranasally in 6 etherized mice. The 50 per cent end point is then calculated by the method of Reed and Muench (1938), taking as the end point of the titration death, or any desired degree of pulmonary consolidation, arbitrarily scored as from ± to ++++, occurring within 10 days of inoculation Horsfall (1939) has elaborated this type of test somewhat by calculating both the 50 per cent mortality end point and the 50 per cent. maximum score end point In this method account is taken of the extent of lung involvement as well as of death (see also Eaton, 1940 *a*).

A still more elaborate method of titration is that of Lauffer and Miller (1944 *a*) Serial tenfold dilutions are made in 0 1M phosphate buffer, pH7, and 6 successive dilutions, covering the expected end point, are inoculated intranasally in mice in 0 05 c.c. amounts. After 10 days, survivors are autopsied The degree of involvement of the lungs is scored as follows no consolidation, –, slight consolidation ±,

seen in purified virus preparations, these particles occur abundantly in control preparations from normal allantoic fluid, and would not appear to be related to the virus itself (Taylor *et al*, 1943 *b*).

Filtration

The virus passes the following simple filters: Seitz, Berkefeld V and N (Francis, 1934), Chamberland L_2 and L_5 (Brightman, 1936, Dujarric de la Rivière and Chevé, 1937 *a, b*)

Gradocol membranes are more widely used in preparing infective filtrates Using these membranes Elford, Andrewes, and Tang (1936) estimated the size of virus A and swine influenza to be between 80 and 120 mμ Friedewald and Pickels (1944) made confirmatory observations using the PR8 and Lee (B) strains

Virus is adsorbed by various earths and clays used in filters, the adsorbed virus can be recovered by treatment with a protein solution such as broth, serum, or isinglass (Hare and Curl, 1947)

Centrifugation

The behavior of influenza virus preparations when exposed to centrifugal force has been extensively studied An air turbine instrument of the Bauer and Pickels type has been much used, and the Sharples centrifuge can also be employed (see, e g, Stanley, 1944 *a*). When centrifuged in electrolytic solutions the rate of sedimentation is often irregular, presumably due to convection or mechanical disturbances Friedewald and Pickels (1943, 1944) have introduced a synthetic density gradient technique with sucrose solutions, sedimentation behavior is more regular in this medium (see also Stanley, 1944 *b*)

The fractions that can be isolated from virus preparations, especially allantoic fluid are 3—the elementary body, the soluble substance, and another complement fixing component known as < 30 S The elementary body, which possesses all the attributes of infectivity, is often known as the 600 S component, although the sedimentation constant varies somewhat with the type and presumably the technique employed The soluble substance has a sedimentation constant of 30 S The properties of the 3 components have been fully described above (see Ch. LVI)

The size of influenza virus can be calculated from sedimentation data Elford and Andrewes (1936) estimated the size of virus A to be between 87 mμ and 99 mμ. The results obtained by various later workers are in agreement with this estimate As regards the elementary bodies of virus A, sedimentation constants of from 600–724 S have been obtained, giving estimates of the particle diameter from 70–100 mμ (Taylor *et al.*, 1943 *b*, Beard *et al*, 1944, Friedewald and Pickels, 1944, Lauffer and Miller, 1944 *b*, Stanley, 1944 *a, b*, Lauffer and Stanley, 1944, Sharp *et al*, 1944 *b, c*, Knight, 1945, 1946 *a*)

The sedimentation constant of virus B seems to be higher (832 S), giving a size of 85–100 mμ (Sharp *et al*, 1943, 1944 *b, c*, Beard *et al*, 1944, Friedewald and Pickels, 1944)

Swine influenza viru [illegible]
found to be from 622– [illegible]
1944, Taylor *et al*, 194 [illegible]

The calculation of [illegible] re-
quires an estimate of various other biophysical properties. Lauffer and Stanley (1944), for example, give the following figures (PR8 strain). specific volume, 0 79, density in sucrose, 1 18, without sucrose 1 1, intrinsic viscosities, 11 3–16 5, water content, 60 per cent by weight More recently Sharp *et al* (1944 *a*, 1945), have introduced an improved technique in which the virus is centrifuged in bovine albumin This appears to give more regular results than centrifugation in sucrose The densities observed by this method were lower than those obtained by the sucrose technique They postulate that when virus is suspended in sucrose, water

CHAPTER LVIII

PHYSICAL AND CHEMICAL PROPERTIES OF INFLUENZA VIRUS

MORPHOLOGY AND BIOPHYSICAL PROPERTIES

Elementary Bodies

IT HAS *already been explained that influenza virus consists of elementary bodies* and a soluble substance. The elementary bodies are probably composed of several antigens as well as containing some SS, and material derived from the host. It has been suggested by Sharp *et al.* (1945)[1] that the elementary bodies are surrounded by a semipermeable membrane, as is found in bacterial cells. The elementary bodies of influenza measure about 100 mμ as has been determined by various methods (to be described). When stained, therefore, these bodies may be just visible with ordinary microscopic equipment. Gordon (1922) demonstrated small granules, 0.2 μ in diameter, in the secretions in the early stages of influenza, and more recently Japanese workers have studied similar bodies. They have found elementary-body-like granules in smears from the lung lesions of mice, and have concentrated them by centrifugation (Tsurumi and Ogasawara, 1940, Tsurumi, Ogasawara, and Fujii, 1941, Tsurumi *et al.*, 1941 *a*). These granules grow in tissue culture and form intracytoplasmic inclusions, they can be agglutinated by antiserum (Tsurumi *et al*, 1941 *b*)

Characteristic inclusions have not been described except by the Japanese workers.

Electron Microscopy

All 3 influenza viruses have been studied by electron microscopy, using as a rule material purified by centrifugation from infected allantoic fluid

Virus A elementary bodies appear to be rounded, ovoid, with a definite tendency to kidney or bean shape, they often occur in aggregates, and may show areas of greater density. Slightly varying estimates of the diameter of these particles have been made 78–80 mμ (Taylor *et al*, 1943 *b*, Beard *et al.*, 1944), and 100 mμ (Lauffer and Stanley, 1944, Knight, 1944 *c*, 1945, 1946 *a*).

An earlier estimate of a much smaller size has been explained by the presence of larger particles as a contaminant (Chambers and Henle, 1943, Chambers *et al*, 1943, Henle and Wiener, 1944).

Virus B elementary bodies appear rounded or ovoid, and have been estimated to measure 97–98 mμ (Sharp *et al*, 1943, 1944 *b*, *c*, Beard *et al*, 1944)

The swine influenza virus has also been studied, and appears to be rounded or *ovoid, measuring 77–78 mμ in average diameter (Beard et al.*, 1944, Sharp *et al*, 1944 *c*, Taylor *et al*, 1944 *b*).

The new gold-shadowing technique gives very striking pictures, and small clusters and chains can be seen (Williams and Wyckoff, 1945, Stanley, 1946) Mosley and Wyckoff (1946) describe the presence of elongated forms, as well as spheres. The elongated forms occur more frequently, and are longer, in preparations made from the Weiss strain. These rod-like forms may be in clumps together with spheres, or may lie separately, occasionally they lie in tangled masses. Most of the long forms show swellings, terminal, or bud-like. Several spheres may be attached to one rod. Normal allantoic fluid does not present these appearances

In addition to the elementary bodies, smaller particles, about 15 mμ, have been

[1] References are appended at the conclusion of Ch LXIII, p 671 et seq

The iso-electric point of Knight's normal allantoic protein is 2.3, and of normal mouse lung particles around 4.2 (Knight, 1946 *a*).

PURIFICATION AND CONCENTRATION

Influenza virus has been isolated in a high state of purity from mouse lungs and allantoic fluid. The following are the chief methods.

Purification by Freezing and Thawing

When allantoic fluid is frozen, and then carefully thawed, a fluffy white precipitate forms which goes into solution at 37° C From 75–95 per cent. of the virus is carried down on the precipitate, and can be eluted therefrom (Hare, McClelland, and Morgan, 1942, Hirst, Rickard, and Whitman, 1942)

Maximum yields of virus are obtained using a phosphate or citrate buffer at pH5 5 Some nonvirus material also goes into solution, but this is reduced to a minimum if the allantoic fluid is adjusted to pH8.8 (with NaOH) before freezing.

Purification by Adsorption to, and Elution from, Red Cells

Francis and Salk's (1942) method is widely used. In their original method chorioallantoic vessels are deliberately torn during the harvesting of the allantoic fluid. The red cells

is eliminated

A definite correlation exists between the cell concentration and the amount of virus adsorbed Thus Hare, Curl, and McClelland (1946) found that the amount adsorbed rapidly decreases when the cell concentration is below 1 per cent. Using a 2 per cent suspension, virtually all A and B virus is adsorbed. Within limits, variation in the volume of the eluting fluid does not affect the yield of virus, although of course altering the titer Under laboratory conditions, the efficiency of recovery of virus by the combined

13–80 per cent.

t 20,000 g for

virus can be

cent. of the

original infectivity (Sharp *et al.*, 1943, 1944 *b*; Beard *et al*, 1944).

Knight (1945, 1946 *a*), obtained a purified preparation of PR8 virus from mouse lungs by a technique involving storage at −70° C, thawing of the suspension, addition of chick red cells, elution in phosphate buffer at 37° C for 90 minutes, and final centrifugation of the eluate These preparations gave 50 per cent. end-points at 10^{-12} to $10^{-11.8}$ and 10^{-12} to $10^{-14.2}$ gm. of nitrogen in mice and chicks respectively The highest chick cell agglutinating activity of mouse lung preparations was 30,000 units per mgm of nitrogen Material obtained from allantoic fluid by similar means gave 50 per cent. end points in chicks of $10^{-14.3}$–$10^{-14.4}$ nitrogen, and in mice of $10^{-9.9}$–10^{-10} gm The chick cell agglutinating activity of these preparations was 40,000 units per mg of nitrogen He found that mouse lung virus has essentially the same properties as allantoic fluid virus, and is precipitated strongly by antiserum to PR8 grown in the allantoic cavity

Purification by Chemical Precipitation

1 Salk's method Virus can be adsorbed, e g, from a mouse lung suspension, by a

water (Salk, 1941, Schaeffer, 1942)

The calcium phosphate precipitate must be formed in the presence of the

To obtain the best yields by this method, the virus-containing material should

purified by differential centrifugation (Stanley, 1945 *a*)

2 Potassium urate adsorbs virus from allantoic fluid without loss

manovich, Parodi, and Chialvo, 1942 3)

3 Virus can be precipitated by alum, and the precipitate redisso'

is removed. It appears as if virus particles are surrounded by a semipermeable membrane permeable to sucrose but not bovine albumin. This membrane is similar in certain properties to the cell wall of bacteria. Particles placed in sucrose would first lose water and thus increase in density. At the same time sucrose would be in sufficient concentration to reverse the flow of water, this would result in a subsequent decrease in density. These authors have obtained the following figures in their studies of PR8, Lee, and swine viruses

TABLE 24

	PR8	*Lee*	*Swine*
Sedimentation constant	742	840	727
Density in aqueous suspension	1.104	1.104	1.100
Diameter calculated by cfg (in mμ)	*116*	*124*	*117*
Partial specific volume	0.822	0.863	0.850
Water content, per cent by volume	52.0	34.5	43.3

These figures for size are larger than obtained by workers mentioned above, and this can be explained by the different technique. The smaller estimates alluded to above were obtained with partly dehydrated particles, whereas in bovine albumin the particles can be regarded as fully hydrated.

Light Absorption

Virus solutions exhibit visible opalescence due to light scattered by virus particles. The molecular weight (M) of uniform spheres such as virus particles = $1.69 \times 10^{24} \dfrac{D\lambda^4}{c\left(\dfrac{\partial n^2}{\partial C}\right)^2}$ where D is the optical density, λ the wave length of light, c the concentration of particles in grams per c.c. of solution, and n *the index of refraction* (Oster, 1946). Using virus obtained from allantoic fluid, the MW was found to be 322 million, using a figure for density of 1.1, the diameter could be calculated at 97 mμ.

Analytical Diffusion

Bourdillon (1941), working with mouse lung preparations infected with virus A, found 99 per cent of the infectivity to reside in particles 200 μμ in diameter, and 1 per cent in particles measuring 6 mμ.

Electrochemical Behavior

Electrophoresis Bourdillon (1940) investigated the electrophoretic mobility of virus A and found it to be -5.5×10^{-5} c.m^2 volt^{-1} sec^{-1} at pH7–9, ionic strength 0.1, at pH10, ionic strength 0.04, it was about -8×10^{-5}.

Miller, Lauffer, and Stanley (1944) investigated the electrophoresis of crude preparations of PR8 obtained by high speed centrifugation. They identified 2 components One component, present to the extent of 80–90 per cent, represented the active virus, and could be separated from the other component by repeated fractional centrifugation, when it appeared homogeneous in the analytical centrifuge, and the Tiselius apparatus, the iso-electric point was at pH5.3 The second component, present to the extent of 10–20 per cent, was identified as an impurity similar to, or identical with, the substance isolated by Knight from normal uninfected as well as infected embryos

Iso-electric point Knight (1945, 1946 *a*) investigated purified PR8 virus obtained from mouse lung, and found that it had two electrochemical natures, one tending towards an iso-electric point at pH5.4, and the other at 7, pH5.4 is the iso-electric point of purified virus obtained from allantoic fluid As just mentioned, Miller, Lauffer, and Stanley (1944) obtained a figure of

polysaccharide composed of mannose, galactose, and glucosamine units. It was tentatively suggested that the latter component was derived from the host alone.

Knight (1947 *b*) attempted to discover a chemical basis for the similarities and differences between the PR8 and the Lee strain. Hydrolysates of the purified viruses were obtained, and assays made for amino acid content. No significant differences were observed with respect to the values for alanine, aspartic acid, glycine, histidine, isoleucine, leucine, methionine, phenylalanine, proline, serine, threonine, and valine. Significant differences were found in the values for arginine, glutamic acid, lysine, tryptophane, and tyrosine. These differences may account for the lack of immunological relationship between the strains, for their different pH stability ranges, their different red cell agglutinating capacities, and the widely divergent heat stability of their hemagglutinins.

A considerable proportion of the volume of influenza virus is occupied by water, which is about 52 per cent. in the case of PR8, 35 per cent. for Lee (B), and 43 per cent. for swine virus (Sharp *et al.*, 1945).

virus can first be concentrated by adsorption on chick cells (Bodily, Corey, and Eaton, 1943)

4. Virus can be precipitated by protamine (Chambers and Henle, 1941).
5 Calcium sulfate also has been used (Tovarnizky and Chalkina, 1944).
6. Virus can be purified with ethyl or preferably methyl alcohol as a preliminary to high speed centrifugation (Cox *et al*, 1946, 1947).

Purification by Electrophoresis

Purification can be effected by electrophoresis (Davoli and Jucker, 1939, Miller, Lauffer, and Stanley, 1944; Tovarnitski and Shishkina).

Purification by Centrifugation

It appears that the most efficient method of purifying virus is by differential centrifugation in a vacuum type of centrifuge, or a Sharples machine. Thus Stanley (1944 *a*) studied the following methods of purification of PR8 grown in the allantoic cavity.

1. Differential centrifugation in a vacuum or Sharples type of centrifuge.
2 Adsorption to, and elution from, adult chick red cells
3 Elution of the precipitate formed on freezing and thawing of the allantoic fluid
4 By adsorption to, and elution from, the chick red cells of the egg yielding the allantoic fluid.
5 Combinations of (1) with (2), (3), and (4).

He found that No. (1) was the most efficient, and yielded much less nonspecific protein He obtained a fairly homogeneous compound with a sedimentation constant of 600 S Such preparations possessed about 22,000 chick cell agglutinating units per mg of protein nitrogen, and the 50 per cent infectivity end-point in chick embryos was 10^{-11} gm

McLean *et al* (1945 *d*) concentrated swine virus by centrifugation in the Sharples instrument. The average infectious unit of virus when inoculated in 0 05 c c volumes in chick embryos was $10^{[illegible]}$ gm of virus, $10^{[illegible]}$ gm gave the ++ end-point in CCA tests The degree of concentration was 130 times, and the yield of virus of 2 2 mgm per 100 c c. of allantoic fluid

CHEMICAL COMPOSITION

Various workers have analyzed the chemical composition of all 3 strains of influenza virus isolated from mouse lung or allantoic fluid. Such preparations contain nitrogen, phosphorus, carbohydrate, fat-solvent extractive (neutral fat, phospholipoid, and cholesterol), nucleic acid (desoxypentose type) (Beard *et al*, 1944, Cohen, 1944, Sharp *et al*, 1944 *b*, Taylor, 1944, Taylor *et al*, 1944 *b*, Knight, 1946 *a*, Miller, 1947)

Slight differences have been detected in the composition of the 3 main strains The main difficulty in this work is the closely similar chemical composition of normal allantoic protein, and normal mouse lung particles Thus Knight (1946 *a*) gives the following details concerning the chemical composition of virus purified from 2 sources, compared with the composition of normal material.

TABLE 25

	PR8 Purified from Mouse Lung	*PR8 Purified from Allantoic Fluid*	*Normal Allantoic Protein*	*Normal Mouse Lung Particles*
Nitrogen per cent	10 1	10 2	9	6 9
Phosphorus per cent	1 06	0 92	0 81	1 4
Carbohydrate as glucose	6 2	6 5	7 7	3 5
Alcohol-ether extractable substance	38 (approx)	26 8	22 4	
Ribonucleic acid	+	+	+	+
Desoxyribonucleic acid	+	+	+	doubtful

In later observations Knight (1947 *a*) obtained both ribonucleic and desoxyribonucleic acids from purified PR8 particles These particles contained carbohydrate additional to that of nucleic acids Lee and PR8 particles seemed to contain a

embryos showed numerous hemorrhages in the muscles, skin, and brain. The WS strain also has been fully adapted to the chorio-allantois (Burnet and Lush, 1938 *b*). The strain underwent a sharp increase in titer between the 41st and 50th passages The foci were then particularly liable to be surrounded by "secondaries." When titrated by pock-counting, there is a simple linear relationship between the concentration of virus (WS egg) and the number of foci produced (Burnet and Faris, 1942).

Virulence of egg viruses. Burnet (1936 *a*) found that his egg passage M virus was only slightly virulent for ferrets. After intranasal inoculation, although there were no symptoms, the animal became resistant to infection and developed immune bodies (Burnet, 1937 *a*) Egg passage M virus was found to be devoid of pathogenicity for man on intranasal inoculation (Burnet and Lush, 1938 *a*).

Although M egg virus was originally thought to be avirulent for mice, it later appeared that this was not so (Burnet and Lush, 1938 *b*, see also Burnet, 1938). It was found that a proportion of mice inoculated intranasally with this virus died after the 8th day, and might show consolidation of the lungs. It was possible to passage egg virus through mice, when much of the pathogenicity for the egg was lost, and the strain became a normal mouse passage one.

Beveridge and Burnet (1946) report that the properties of the fully adapted Melbourne strain are now as follows it is nonpathogenic for mice and ferrets, it has almost lost the power to agglutinate fowl and pigeon cells, but agglutinates guinea-pig cells, it grows poorly in the allantoic cavity, antigenically it is still close to the mouse-adapted strain, although minor differences are recognizable. The Melbourne Egg strain probably should be regarded as a distinct phase of equal status with O and D

Burnet, Keogh, and Lush (1937) developed a strain EM which produced lesions in the egg while still affecting the mouse This strain was produced from egg passage virus by a few mouse passages, thereafter the strain was passed irregularly both through mice and eggs. This strain could be titrated either on the egg membrane or by its effect on the mouse.

The virulence of WS egg virus for animals has been described by Burnet and Lush (1938 *b*) In contrast to the reactions of M egg virus, WS egg virus has retained some virulence for ferrets, producing mild symptoms and a temperature rise at 48 hours The WS egg virus is also virulent for mice, and resembles the EM strain in that it can be titrated on the egg membrane and in the mouse. Stuart-Harris (1939) has produced a neurotropic variant of WS by egg passage After passage the chick embryos developed hemorrhagic encephalitis, chick embryo brain was then injected intracerebrally in mice, and after a number of passages these animals developed a fatal encephalitis

Swine virus infections This virus can be grown on the chorio-allantois (Kobe and Fertig, 1938) The synergistic effect of *H suis* and swine virus could be reproduced on the chorio-allantois Recently isolated and old stock strains of *H. suis* worked equally well, and even heat-killed cultures could be used, 2 strains of human influenza virus failed to substitute for *H. suis* (Bang, 1943 *a*).

Use of the chorio-allantois in influenza research.

1 Virus can be titrated by pock-counting on the chorio-allantois (Burnet, 1936 *a*, *b*, *c*, Burnet and Faris, 1942)

2 The egg membrane has been found to yield an effective antigen for use in the complement fixation test (Lush and Burnet, 1937, Hoyle and Fairbrother, 1937 *c*)

CHAPTER LIX

CULTIVATION OF INFLUENZA VIRUS

TISSUE CULTURE

VIRUS has been grown in media composed of chick embryo and Tyrode's solution (Francis and Magill, 1935 *a*,[1] 1935–6, 1937 *a*, Smith, 1935; Magill and Francis, 1936, 1936–7, 1937; Francis, 1937, Stokes *et al.*, 1937 *b*, Tulloch, 1939; Eaton, 1940 *a*, Tsurumi *et al.*, 1941 *b*; Andrewes, 1942 *c*; Packaleú, 1946). Cultured virus is said to retain its antigenic properties and its pathogenicity.

Chick embryo lungs, kidney, and spleen can be used as the source of tissue (see Burnet and Clark, 1942).

Virus A has also been cultivated in roller tube cultures using embryonic lung, or the lung of 2-day-old chicks, a higher concentration of virus was found in the tissue portion than in the nutrient fluid, but the titers of both portions remained almost constant from about the 5th–30th days (Enders and Pearson, 1941, Pearson and Enders, 1941).

Cultures prepared by Dochez, Mills, and Kneeland (1934–5, 1936) were said to produce clinical influenza on inoculation into volunteers. In earlier work (1932–3) by these authors, cultures prepared from cases of influenza had produced only common colds on human inoculation.

It has been reported (Francis and Magill, 1937 *c*) that virus may be cultivated directly from filtrates of human throat washings by inoculation of tissue cultures

Tissue cultures have also been used to study the effect of antiserum and virus on cells (see p. 648), to immunize human beings (see p. 658), and to serve as antigen in complement fixation tests (see p. 649).

The Interference Phenomenon

Andrewes (1942 *a*) has studied the interference phenomenon in tissue cultures He cultivated virus A, and added a different strain of the same type 24 hours later. The first virus interfered with, and prevented the growth of, the second. This interfering effect of the first strain did not prevent multiplication of LGI virus added later. The strain of virus added first, interfered with the growth of the second If the two strains were added simultaneously the one present in the larger amount suppressed the growth of the other

Lennette and Koprowski (1946) made the interesting observation that a tissue culture strain of yellow fever (17 DD High) and the West Nile virus suppressed and interfered with the growth of PR8 in tissue culture

THE EGG

Practically all work has been carried out with hen eggs, but duck eggs can be used for certain purposes (Beveridge and Burnet, 1946)

The Chorio-Allantoic Membrane

Influenza virus A can be cultivated on the chorio-allantoic membrane (Smith, 1935, Burnet, 1935 *b*, 1936 *a*, *b*, *c*, *d*, 1937 *a*, Badenski and Bruckner, 1937, Hoyle and Fairbrother, 1937 *c*, Tsurumi, Ogasawara, and Takagi, 1939)

Adaptation to the chorio-allantois. It is not easy to adapt strains fully to the chorio-allantois, and only the Melbourne and WS strains have been so adapted Certain other strains produce foci, but do not kill the embryo (Beveridge and Burnet, 1946). Burnet (1936 *a*) has made a particular study of the effect of his

[1] References are appended at the conclusion of Ch LXIII, p 671 et seq

. . . ds definite isolated
. . . was killed on the
. . . ed a hemorrhagic
. . . to 44 hours. Such embryos showed numerous hemorrhages in the muscles, skin, and brain. The WS strain also has been fully adapted to the chorio-allantois (Burnet and Lush, 1938 *b*). The strain underwent a sharp increase in titer between the 41st and 50th passages. The foci were then particularly liable to be surrounded by "secondaries." When titrated by pock-counting, there is a simple linear relationship between the concentration of virus (WS egg) and the number of foci produced (Burnet and Faris, 1942).

Virulence of egg viruses. Burnet (1936 *a*) found that his egg passage M virus was only slightly virulent for ferrets. After intranasal inoculation, although there were no symptoms, the animal became resistant to infection and developed immune bodies (Burnet, 1937 *a*). Egg passage M virus was found to be devoid of pathogenicity for man on intranasal inoculation (Burnet and Lush, 1938 *a*).

Although M egg virus was originally thought to be avirulent for mice, it later appeared that this was not so (Burnet and Lush, 1938 *b*, see also Burnet, 1938) It was found that a proportion of mice inoculated intranasally with this virus died after the 8th day, and might show consolidation of the lungs. It was possible to passage egg virus through mice, when much of the pathogenicity for the egg was lost, and the strain became a normal mouse passage one.

Beveridge and Burnet (1946) report that the properties of the fully adapted Melbourne strain are now as follows it is nonpathogenic for mice and ferrets, it has almost lost the power to agglutinate fowl and pigeon cells, but agglutinates guinea-pig cells, it grows poorly in the allantoic cavity; antigenically it is still close to the mouse-adapted strain, although minor differences are recognizable. The Melbourne Egg strain probably should be regarded as a distinct phase of equal status with O and D.

Burnet, Keogh, and Lush (1937) developed a strain EM which produced lesions in the egg while still affecting the mouse This strain was produced from egg passage virus by a few mouse passages, thereafter the strain was passed irregularly both through mice and eggs This strain could be titrated either on the egg membrane or by its effect on the mouse.

The virulence of WS egg virus for animals has been described by Burnet and Lush (1938 *b*). In contrast to the reactions of M egg virus, WS egg virus has retained some virulence for ferrets, producing mild symptoms and a temperature rise at 48 hours The WS egg virus is also virulent for mice, and resembles the EM strain in that it can be titrated on the egg membrane and in the mouse Stuart-Harris (1939) has produced a neurotropic variant of WS by egg passage. After passage the chick embryos developed hemorrhagic encephalitis, chick embryo brain was then injected intracerebrally in mice, and after a number of passages these animals developed a fatal encephalitis

Swine virus infections This virus can be grown on the chorio-allantois (Kobe and Fertig, 1938) The synergistic effect of *H. suis* and swine virus could be reproduced on the chorio-allantois Recently isolated and old stock strains of *H suis* worked equally well, and even heat-killed cultures could be used, 2 strains of human influenza virus failed to substitute for *H. suis* (Bang, 1943 *a*).

Use of the chorio-allantois in influenza research.

1 Virus can be titrated by pock-counting on the chorio-allantois (Burnet, 1936 *a*, *b*, *c*, Burnet and Faris, 1942).

2. The egg membrane has been found to yield an effective antigen for use in the complement fixation test (Lush and Burnet, 1937, Hoyle and Fairbrother, 1937 *c*).

3. Virus grown on the egg can be used to immunize animals (Burnet, 1937 *a*, 1938), and man (Burnet and Lush, 1938 *a*).

4. The egg can be used, it has been reported, for the direct isolation of virus, without preliminary animal passage, from nasopharyngeal washings (Francis and Magill, 1937 *c*; Hyde and Chapman, 1937).

5. The egg can be used as an indicator of virus neutralizing properties. The virus and serum under test are mixed and inoculated in the egg. The capacity of the serum for preventing the development of pocks is noted, and forms an estimate of its immune body content (Burnet, 1936 *a*, Burnet and Lush, 1938 *a*).

6. The egg has been used extensively to study the academic problem of the antigen-antibody reaction in influenza (Burnet, 1936 *d*; Burnet, Keogh, and Lush, 1937).

Allantoic Inoculation

Influenza virus proliferates readily in the allantoic membrane, and is found in large amount in the allantoic cavity; this route of inoculation is widely used in influenza work (Burnet, 1941 *c*, 1942 *b*; Henle and Chambers, 1941; Hirst, 1941, Nigg, Wilson, and Crowley, 1941, Eaton *et al*, 1942; Beveridge and Burnet, 1946).

Both types of human virus and swine virus grow well in the allantoic cavity, with the proviso that freshly isolated strains in Burnet's O phase may only do so [illegible] (see Ch. LVI).

[illegible] that influenza virus A and B will proliferate in [illegible] ly infected in the yolk sac with typhus *Rickettsiae* (Breinl and Castaneda strains)

Preliminary incubation. It is customary to inoculate eggs already incubated for 10 days at about 38–39° C., but Beveridge (1944 *a*) found that embryos incubated at 36.6 to 37.8° C. give about twice as much allantoic fluid as those incubated at 39° C., and infection was secured more readily. If older eggs are used, trouble is experienced with the heavy precipitate of urates.

Inoculum As mentioned earlier (see p. 583) virus can be isolated by inoculation of throat washings, with or without preliminary treatment to reduce contaminants, directly into the allantoic cavity, in which case a volume of 0.15 to 0.2 c.c. is used

When passage strains are inoculated, it is best to use weak dilutions, 10^{-3} to 10^{-5}, as interference may result with more concentrated inocula (see p 621) Volumes of 0.05 c.c. to 0.2 c.c. are usually used. Whether or not infection occurs, depends on the amount of virus introduced into the allantoic fluid, and not on the volume of the inoculum (Taylor et al., 1944 *a*).

Temperature after inoculation Better virus yields are obtained when the eggs are incubated after inoculation at 35–36° C rather than higher temperatures (Miller, 1944 *a*, McLean *et al*, 1944, 1945 *a*, Sigurdsson, 1944) The more acid pH at higher temperatures may be the explanation of this phenomenon

It is usual to incubate for 40–48 hours

Evidences of infection The presence of infectivity is most easily judged by the occurrence of agglutination when allantoic fluid is mixed with a chick red cell suspension Allantoic fluid usually gives a titer of 1 256, 1 512 or 1/1024 with 1.5 or 2 per cent chick cells A high titer may be found even after 12 hours (Henle and Chambers, 1941) The fluid of eggs inoculated with untreated washings may cause a nonspecific agglutination of fowl cells, up to 1 160, due to the presence of cocci or *B subtilis* (Florman, 1946) Infectivity can also be tested by mouse inoculation or inoculation into a fresh series of allantoic cavities Infectivity is maximal after 48 hours incubation and may reach 10^{7} (Burnet, 1941 *c*) The concentration of virus particles in untreated allantoic fluid has been calculated at 0.01 per cent (Friedewald and Pickels, 1944)

The injection of undiluted infected allantoic fluid, irradiated for 3–5 minutes,

in 8-day embryos, did not prove lethal, but the allantoic sacs frequently failed to develop further, when fluids were irradiated for 15 minutes or more, no inhibition of growth of the sacs was produced, nor did the fluids act as interfering agents (see below), however, virus particles were adsorbed onto allantoic cells regardless of the time of exposure to UVL (Henle and Henle, 1947)

The presence of virus can be shown indirectly by using the fluid as an antigen with known sera in neutralization, or complement fixation tests The peak of complement fixing activity occurs after 36 hours, and that of flocculability after 48 hours (Henle and Chambers, 1941).

The pH values of allantoic fluids from noninfected eggs show a rapid drop from the 12th–17th day of development In contrast, the allantoic fluid of influenza-infected eggs gives pH values remaining relatively stable about the neutral point between 11 and 17 days, the Eh of normal fluid usually shows a positive potential, but there is a marked state of reduction accompanying virus growth, with a predominantly negative potential (*U.S Nav Med Lab.* No 1, 1945)

Embryos are seldom killed after allantoic inoculation, but the chorio-allantois adapted Melbourne and WS strains usually kill within 48 hours, with widespread hemorrhages in muscles and brain (Beveridge and Burnet, 1946).

Distribution of virus After allantoic inoculation, virus reaches all parts of the egg, including the amniotic fluid, embryo, and even the yolk sac (see Pearson, 1944 *a*). Virus grows in the allantoic entoderm and the cells may show degenerative changes (Burnet, 1941 *c*).

Risk of contamination. The healthy embryo is relatively resistant to infection with bacteria, and contamination during routine passage experiments is unusual. It appears, however, that with the swine strain there is an increased susceptibility to infection (Taylor *et al.*, 1945).

Titration by allantoic inoculation Influenza virus preparations can be titrated by the inoculation of falling dilutions in a series of allantoic cavities. The presence of infectivity is judged by the agglutination of red cells, 50 per cent. end-points can be worked out by Reed and Muench's (1938) method. For example, Hirst (1942 *a*) injects serial tenfold dilutions of the virus, made in horse-serum broth, into the allantoic cavity, 6 eggs being used for each dilution, and incubated at 37° C. for 42 hours After chilling at 4° C for 3–4 hours, the allantoic fluid is aspirated from the air sac end The presence of virus is detected by mixing equal (e g, 1 c c.) quantities of pure allantoic fluid and chick cell suspension, and examining for agglutination after an hour. This method proves more sensitive than the inoculation of mice, and is equally useful for mouse-adapted and recently isolated strains

Knight (1944 *b*) found that high degrees of accuracy are obtained with 10 embryos, enabling twofold differences to be recognized, but that sufficient accuracy results from the use of half that number (recognizing fourfold differences). He also confirmed that the embryo is sensitive to considerably smaller amounts of virus than can cause infection of mice.

Uses of allantoic inoculation.

1 For the isolation and characterization of strains from throat washings (see p 591)

2 For passage of strains in the laboratory.

3 For titration experiments (see above)

4 For obtaining large quantities of crude virus that can be purified to study its biophysical and biochemical properties (see Ch LVIII).

5 Allantoic fluid is the commonest source of virus for use in influenza vaccine (see Ch LXIII)

6 Allantoic fluid can be used as an antigen in complement fixation tests (see p 649), or in virus neutralization tests (see p. 647).

7. For studying problems such as the interference phenomenon (see p. 621), or the neutralization of virus by antisera.

8. For chemotherapeutic experiments (see p. 627).

Amniotic Inoculation

Inoculation of influenza virus into the amniotic cavity was introduced by Burnet (1940 *a*, *b*). Burnet, his colleagues, and others have since used the method extensively (see, e.g., Burnet, 1941 *a*, 1942 *a*, Burnet and Foley, 1940, 1941 *b*, *c*; Burnet *et al.*, 1942, Eaton *et al.*, 1942; Taylor and Chialvo, 1942; Burnet, Beveridge, and Bull, 1944; Burnet and Stone, 1945 *b*, *c*, Beveridge and Burnet, 1946, Burnet, Stone, and Anderson, 1946).

The technique can be used for the primary isolation of strains from throat or nasal washings, as well as for passage of laboratory strains. Special precautions are necessary to prevent O phase virus entering the D phase (see p. 595). Various methods have been introduced for the actual inoculation, and these are fully described in Ch. XIII

Incubation and inoculation. It is usual to use eggs incubated for 13–15 days before inoculation. The temperature of incubation before inoculation has no influence on the susceptibility to virus A or B (Beveridge, 1944 *a*). Burnet, Beveridge, and Bull (1944) found that 8–10-day embryos were more sensitive in detecting limiting dilutions of an unadapted B strain (Bon), but a number of B strains isolated in 1945 infected 13-day embryos (Beveridge and Burnet, 1946). As regards the inoculum, this should be as dilute as possible, especially when it is desired to maintain virus in the O phase. Eggs inoculated with virus A should be examined after 48–72 hours, but those inoculated with virus B should be left for 5 days, owing to the slower development of the virus.

Distribution of virus after amniotic inoculation. Virus can be detected in the allantoic fluid as well as the lungs, tracheal fluid, and amniotic fluid It appears as if virus inoculated into the amnion is swallowed, some reaching the trachea where proliferation occurs. Virus from the trachea is swallowed and passes through the alimentary canal to reach the allantoic cavity (Burnet, 1940 *b*). Virus probably proliferates in the pharynx also.

Evidence of infection. Both amniotic and allantoic fluids contain virus, and give agglutination of chick red cells The embryo shows striking changes, and the following description is largely taken from that of Burnet (1940 *a*, *b*). The changes are similar with O and D phase (Beveridge and Burnet, 1946) We have ourselves confirmed these changes, and paid particular attention to the histological appearances

The embryo is usually underdeveloped and after 3 days many will be moribund or actually dead The tracheal fluid should be removed, centrifuged, and films of the deposit stained by Leishman's method (see Ch XIII for technique involved). This fluid is turbid and contains granular clumps Microscopic examination shows the presence of vacuolated epithelial cells (12–20 μ in diameter), deriving chiefly from the parabronchi, also leukocytes, and immature red cells with disintegrated nuclei. The vacuolated cells may contain granular eosinophilic material With a large inoculum, the tracheal fluid may show these appearances after 24 hours, and will certainly do so after 48 hours, with unadapted strains, changes may not be evident for 4–6 days, and even then be only slight.

The lungs appear to be whiter than normal, and more firm The main changes are to be found histologically, and are similar with viruses A and B (Burnet, 1940 *a*, *b*, 1942 *a*, Fodden and Rhodes) The earliest lesions occur in the parabronchi, with involvement of the epithelial cells The nuclei show signs of degeneration, later there is much cellular proliferation, and the epithelium desquamates, to fill the lumen. The saccular outgrowths from the parabronchi become disorganized,

and so does all the lung tissue. The endothelial lining of the blood vessels surrounding the parabronchi proliferates. Numerous leukocytes are found at a late stage.

Titration of viruses by the amniotic route. Viruses can be titrated by amniotic inoculation, and the method is as sensitive as mouse inoculation (Burnet, 1941 *a*). Fifty per cent. end-points can be calculated, evidence of infection being indicated by the occurrence of chick cell agglutination with the amniotic fluid.

The effect of passage. Unless special precautions are taken, as described on p 595, virus passed by the amniotic route will enter the D phase. As regards virulence, Burnet and Foley (1941 *b*) studied the changes in activity of 2 strains (Bundoor and R). They found a rapid increase in virulence for the embryo, with a shortened survival period The power to produce signs in ferrets progressively diminished, but the immunizing potency was unaltered

Uses of amniotic inoculation.

1. For the isolation of strains from human material (see p. 583).
2. For passage of strains in the laboratory.
3. For titration experiments
4. For studying academic problems such as the pathological effects produced by influenza virus, or the neutralization of virus by antisera.

Inoculation by Other Routes

Virus can be isolated from washings by inoculation of the yolk sac of 3–6 day eggs (Beveridge, Burnet, and Williams, 1944), but about 100 times as much virus is needed as will infect amniotically (Beveridge and Burnet, 1946), eggs can be inoculated with filtrates or with raw washings using penicillin and sulfadiazine. Passage strains of influenza A and B can be propagated by this route if desired (Beveridge, 1944 *a;* Burnet, Beveridge, and Bull, 1944). Using a modified technique of yolk sac inoculation, Nigg, Crowley, and Wilson (1940) found that suspensions of yolk sac, chorio-allantois, and amnion yielded excellent antigens for complement fixation

The Melbourne Egg strain infects embryos on intravenous inoculation, producing characteristic hemorrhagic lesions (Burnet and Bull, 1944).

The Interference Phenomenon in Eggs

The interference phenomenon has been studied in eggs, as well as in tissue cultures (see above). The fundamental observations are largely those of Henle and Henle As a rule, virus has been inoculated in the allantoic cavity, and subsequent tests for the presence of virus conducted by means of chick cell agglutination.

I. Interference produced by concentrated single inocula.

Following a single inoculation of virus in the allantoic cavity, some particles may become inactivated, and interfere with the propagation of the remaining viable particles (Henle and Henle, 1943) Thus, if the inoculum used for allantoic inoculation is too concentrated, especially with the Lee (B) strain, the fluid removed after incubation will not give such a high titer in chick cell agglutination tests as would be obtained by the inoculation of more dilute material (Henle and Henle, 1944 *a*). Similarly a greater degree of toxicity is developed in allantoic fluid by inoculation of dilute "seed" (Henle and Henle, 1946 *b*).

When a single inoculum is heated, e g, to 56° C. for 10 minutes, partial destruction of virus takes place. This inactive virus interferes with the growth of the remaining active virus in the same preparation, if the heated material is inoculated "neat" in the allantoic cavity (Henle and Henle, 1944 *a*, Jones, 1945). However, if the heated material is inoculated in a dilution of 10^{-2}–10^{-3}, virus growth takes place more readily (Henle and Henle, 1944 *a*) Similar results were obtained with virus partly inactivated by ultraviolet light

By continued transfer of undiluted inocula Magnus (1946) claims to have produced a variant of PR8 that interferes with the propagation of virus (see also Gard and Magnus, 1946).

2. Interfering effect of one dose of virus upon another.

Under certain conditions, the injection of one strain of virus in the allantoic cavit[illegible] another strain Ziegler and [illegible] ound that the inoculation [illegible] inoculated later. They found that interference is completely reciprocal, if small doses are used for the first as well as second inoculum, small doses of Lee are, however, less effective in preventing large doses of PR8 from growing than the reverse. They also found that the interfering effect depends on the relative dosage of the 2 inocula, and the interval between inoculations. The phenomenon can be reversed; for example, if a large second dose of Lee virus is given up to 8 hours after a first small dose of PR8, then PR8 is inhibited. The interfering factor can be destroyed at 56° C., but resists storage at 4° C. for prolonged periods.

3. Interfering effect of irradiated virus.

(*a*) Most work on the interfering effect has been carried out with material inactivated by exposure to ultraviolet light (UVL). When allantoic fluid is irradiated, the infectivity decreases rapidly, the fluid becomes noninfective when the interfering capacity is reaching its peak. On further irradiation, the interfering property diminishes, and finally disappears, although the hemagglutinating capacity of the preparation is still intact (Henle and Henle, 1945 *d*, 1947).

(*b*) Virus almost completely inactivated by irradiation with UVL interferes with the growth of active virus inoculated 3–4 hours later. Dialyzed fluid is more sensitive to irradiation, and exerts the interfering effect only if irradiated for a much shorter period (Henle and Henle, 1944 *a*, *b*, 1947).

Ziegler, Lavin, and Horsfall (1944) found that the inoculation of highly concentrated preparations of A or B virus interferes with the multiplication of homologous or heterologous virus, inoculated 24 hours later They found a similar interference using virus completely inactivated, although inactive PR8 did not produce marked interference with swine virus

Heterologous interference takes place equally well as homologous. Thus irradiated PR8 prevents the multiplication of active PR8, Lee, or WS injected later (Henle and Henle, 1945 *c*)

(*c*) The dose of irradiated fluid required to interfere is very small, and 0.01 to 0.005 c.c. suppresses the formation of measurable amounts of hemagglutinin from a subsequent inoculation of active virus High concentration of test virus does not overcome this interfering effect (Henle and Henle, 1944 *b*).

(*d*) The factor in UVL-irradiated virus remains active when stored at 4° C for 4 weeks (Ziegler, Lavin, and Horsfall, 1944)

(*e*) There is no striking difference in the interfering property of UVL-irradiated fluid harvested after 24 to 96 hours, although their agglutinating titers vary, the interfering property in fluids harvested at the earlier periods is more susceptible to destruction by UVL (Henle and Henle, 1944 *b*)

(*f*) With regard to the time factor, the interfering injection of UVL-irradiated virus can be given as early as 96 hours before the test virus, or up to 3 hours later (Henle and Henle, 1944 *b*)

4. The site of interference.

The interfering injection appears to act on the cells of the allantoic cavity, and renders them insusceptible to attack by active test virus If the allantoic sac is flushed with saline after the inoculation of the interfering agent, interference still

occurs The protection of susceptible cells takes place so rapidly that even if virus is introduced during the process of flushing, interference still results (Henle and Henle, 1944 *b*).

5. Interference between unrelated viruses.

Irradiated influenza virus interferes with the subsequent growth of western *equine encephalomyelitis virus, and epidemic keratoconjunctivitis virus (Henle and* Henle, 1945 *c*). This need only indicate that both viruses react with the same cell receptors.

6. The nature and mode of action of the interfering agent.

Interference does not result in destruction of virus, and some active virus can be found in fluids when interference has taken place This virus may derive from the interfering injection, if it contains some active virus, or from the test virus which retains its original activity although it cannot proliferate (Henle and Henle, 1944 *b*).

The interfering agent in irradiated preparations appears to be the inactivated virus itself for the following reasons It is sedimented in the centrifuge under conditions that will sediment the active virus It is adsorbed on to, and eluted from, chick red cells in amounts comparable to the virus It is specifically neutralized by immune sera, the interfering agent in virus A preparations is neutralized only by antisera to virus A (Henle and Henle, 1945 *d*).

The interfering injection prevents the test virus from entering the cells and propagating in the allantoic sac; active virus cannot be detected in suspensions of embryonic membranes (Henle and Henle, 1944 *b*).

It is uncertain whether irradiated preparations contain a small amount of active virus or not From the nature of the phenomenon it is difficult to demonstrate the presence of virus in a preparation that effectively prevents its proliferation (Henle and Henle, 1944 *b*) It would appear that for all practical purposes it can be considered that completely inactivated virus acts as an interfering agent. The interfering agent may produce its effect by saturation of receptors on susceptible cells, so that the subsequently introduced test virus cannot "attach" itself and grow, it is possible that the reaction may occur intracellularly and involve enzyme systems (Ziegler, Lavin, and Horsfall, 1944, Henle and Henle, 1945 *c*)

In later work, Henle and Henle (1947) showed that virus particles irradiated for too long (1–2 hours) to permit them to give the interfering effect were still adsorbed to the allantoic cells If the virus had not been irradiated for more than 3–5 minutes, this adsorption resulted in cessation of growth of the allantoic sac, and at the same time the interference phenomenon occurred These observations

(1) adsorption, (2) an alteration occurs in the function of cell, which excludes other viruses, this is perhaps initiated by the entry of a single particle; (3) intracellular proliferation, (4) release of virus

7. The interference phenomenon to demonstrate growth cycles.

Henle, Henle, and Rosenberg (1947) adapted the interference phenomenon to study the growth of virus in the allantoic sac, and found that multiplication is apparently based on general principles similar to those affecting the propagation of bacterial viruses In this work, the PR8 and Lee strains of virus were used.

1 Injection of 1000–10,000 ID 50 of virus in the allantoic sac did not lead to complete adsorption onto the cells of the sac, but between 10 and 30 per cent. of *virus remained free. In the case of PR8, 6 hours, in the case of Lee,* 9–10 hours

By continued transfer of undiluted inocula Magnus (1946) claims to have produced a variant of PR8 that interferes with the propagation of virus (see also Gard and Magnus, 1946).

2. Interfering effect of one dose of virus upon another.

Under certain conditions, the injection of one strain of virus in the allantoic cavity inhibits the multiplication of a subsequent inoculum of another strain. Ziegler and Horsfall (1944) used PR8, Lee, and swine strains, and found that the inoculation of any one strain inhibits the growth of another strain inoculated later. They found that interference is completely reciprocal, if small doses are used for the first as well as second inoculum; small doses of Lee are, however, less effective in preventing large doses of PR8 from growing than the reverse. They also found that the interfering effect depends on the relative dosage of the 2 inocula, and the interval between inoculations The phenomenon can be reversed, for example, if a large second dose of Lee virus is given up to 8 hours after a first small dose of PR8, then PR8 is inhibited The interfering factor can be destroyed at 56° C., but resists storage at 4° C. for prolonged periods.

3. Interfering effect of irradiated virus.

(*a*) Most work on the interfering effect has been carried out with material inactivated by exposure to ultraviolet light (UVL). When allantoic fluid is irradiated, the infectivity decreases rapidly, the fluid becomes noninfective when the interfering capacity is reaching its peak. On further irradiation, the interfering property diminishes, and finally disappears, although the hemagglutinating capacity of the preparation is still intact (Henle and Henle, 1945 *d*, 1947).

(*b*) Virus almost completely inactivated by irradiation with UVL interferes with the growth of active virus inoculated 3–4 hours later. Dialyzed fluid is more sensitive to irradiation, and exerts the interfering effect only if irradiated for a much shorter period (Henle and Henle, 1944 *a*, *b*, 1947).

Ziegler, Lavin, and Horsfall (1944) found that the inoculation of highly concentrated preparations of A or B virus interferes with the multiplication of homologous or heterologous virus, inoculated 24 hours later. They found a similar interference using virus completely inactivated, although inactive PR8 did not produce marked interference with swine virus

Heterologous interference takes place equally well as homologous. Thus irradiated PR8 prevents the multiplication of active PR8, Lee, or WS injected later (Henle and Henle, 1945 *c*)

(*c*) The dose of irradiated fluid required to interfere is very small, and 0 01 to 0 005 c c suppresses the formation of measurable amounts of hemagglutinin from a subsequent inoculation of active virus High concentration of test virus does not overcome this interfering effect (Henle and Henle, 1944 *b*).

(*d*) The factor in UVL-irradiated virus remains active when stored at 4° C. for 4 weeks (Ziegler, Lavin, and Horsfall, 1944)

(*e*) There is no striking difference in the interfering property of UVL-irradiated fluid harvested after 24 to 96 hours, although their agglutinating titers vary, the interfering property in fluids harvested at the earlier periods is more susceptible to destruction by UVL (Henle and Henle, 1944 *b*)

(*f*) With regard to the time factor, the interfering injection of UVL-irradiated virus can be given as early as 96 hours before the test virus, or up to 3 hours later (Henle and Henle, 1944 *b*).

4. The site of interference.

The interfering injection appears to act on the cells of the allantoic cavity, and renders them insusceptible to attack by active test virus If the allantoic sac is flushed with saline after the inoculation of the interfering agent, interference still

CHAPTER LX

REACTION OF INFLUENZA VIRUS TO PHYSICAL, CHEMICAL, AND BIOLOGICAL AGENTS

PHYSICAL AGENTS

Heat

THE INFECTIVITY of virus is destroyed at 56° C in about 20–30 minutes, although the interfering property and chick cell agglutinating property resist. Virus strains can be "trained" to withstand temperatures normally lethal (Jones, 1945).[1]

Storage

Preparations of crude or purified influenza virus (human and swine) derived from mouse lungs or egg fluids can be kept for at least several weeks if desiccated *in vacuo*, preferably from the frozen state, and kept in the refrigerator (Scherp *et al*, 1938, Shope, 1931 *b*, 1934 *b*; Hare, McClelland, and Morgan, 1942) Ferret turbinates can be stored in 50 per cent. glycerol in Ringer for at least a year at 0° C (Burnet and Clark, 1942) We have found that virus in infected allantoic fluid, kept in the ordinary cold room, retains sufficient activity to infect eggs for at least 6 weeks

The most satisfactory method of storage (e g, of allantoic fluid or mouse lung suspension) is in ampules in dry ice at about –60° C. (see, e g, Turner, 1938, Horsfall, 1939, Hirst, 1941). Virus can be maintained easily in amniotic fluid with 30 per cent. glycerol at –10° C. (Burnet and Stone, 1946). Apparently, certain B strains deteriorate rapidly on freezing (Hirst, 1947 *b*).

Simple Desiccation

When infective allantoic fluid of high potency is dried in air on glass it may remain viable and infective for eggs for several days, when mucus is added, the survival time is prolonged for about 7 weeks (Parker, Dunham, and MacNeal, 1944). Virus B was found to be inactivated more quickly than virus A when dried on glass or cellophane (*U.S Nav Med. Lab*, 1942 *b*).

Survival in Fabrics and Dust

Virus can survive when impregnated in a blanket and dried, and it can be distributed in the air or dust by shaking (Edward, 1941).

A small percentage of virus survives when impregnated in fabric and dried in air, in the dark, some virus survives for weeks, but it disappears more rapidly if the materials are kept at 37° C, or in the light (Edward, 1941). Virus has been demonstrated in dust exposed near an infected ferret (Edward, 1941).

Sonic Vibration and Homogenization

Virus A and swine virus are not destroyed by intense sonic vibration, nor does homogenization increase the activity of infected tissue (Scherp and Chambers, 1936–7). As described above (see p 588), sonic vibration results in the partial disintegration of elementary bodies with the release of some soluble substance.

Irradiation

X-ray therapy given to mice infected with swine virus had no effect, therapy administered 48 hours before infection produced a decreased mortality (Dubin, Baylin, and Gobbel, 1946).

[1] References are appended at the conclusion of Ch LXIII, p 671 et seq

elapsed before the concentration of virus began to rise in the fluid. It appeared that during this time virus increased in association with the cells.

2. To obtain "single infection" of cells, small doses of active virus were injected at the onset of the experiments. Then to interrupt the process of adsorption, and to prevent further infection of cells, irradiated heterologous virus was injected shortly after. This virus was shown to produce the interference phenomenon in all remaining susceptible cells, and to prevent further adsorption of virus

The content of virus in the allantoic fluid remained constant for 6–9 hours, then rose steeply for 2 hours (PR8) or 2–3 hours (Lee) From this period on, the active virus titer remained on this higher "plateau" up to 24 hours after injection, when the experiment was ended. By this technique, "one-step growth curves" were thus obtained, closely resembling those of bacterial viruses.

3. Varying the concentration of active virus in the inoculum over a wide range did not result in significant alterations in the one-step curve

4. Calculations showed that for every one ID 50 of virus adsorbed, about 50 were released. It is not known how many virus particles make up one ID 50

5. When homologous irradiated virus was used, the yield of virus was reduced to a considerable extent. The "step" was delayed, and decreased in size. This effect was linked to the virus particle, and was destroyed by prolonged irradiation

6 No information is available as to what happens within the cells during the few hours before virus is liberated. It appears most likely that the virus yielded into the allantoic fluid is released by the destruction of the entodermal cells of the allantoic sac, and histological observations carried out on the allantoic cells seemed to be in agreement with this view.

TABLE 26

SUBSTANCES INACTIVATING INFLUENZA VIRUS

Phenol, 0 5 per cent–3 per cent	Dunham and MacNeal (1944)
Iodine, chlorine, or bromine	Dunham and MacNeal, Knight and Stanley (1944), Stone and Burnet (1945)
Lugol's solution, 1 per cent	Dunham and MacNeal
Mercuric chloride, 1/1,000	Dunham and MacNeal
Potassium permanganate, 1/1,000	Dunham and MacNeal
Copper sulphate, 1 per cent	Dunham and MacNeal
Propylene glycol, 90 per cent	Dunham and MacNeal
Liquor antisepticus (N F.VII) 80 per cent	Dunham and MacNeal
Salts of heavy metals	Knight and Stanley
Mercurochrome	Knight and Stanley
Ascorbic acid	Klein (1945)
Ether (10 per cent is withstood for at least 90 hours)	Sarracino and Soule (1941 *b*)
Bile salts	Smith (1939)
Sodium desoxycholate, saponin	Burnet, Lush, and Jackson (1939)
Sodium lauryl sulfate	Burnet and Lush (1940 *b*)

SUBSTANCES FAILING TO INACTIVATE INFLUENZA VIRUS

Reducing agents	Knight and Stanley (1944)
Glucose	Knight and Stanley
Ammonium sulfate	Knight and Stanley
Calcium chloride	Knight and Stanley
Sodium thiosulfate, arginine	Knight and Stanley

Soaps and Detergents

Stock and Francis (1940, 1943) found that a number of virus strains were effectively inactivated at pH 7 5 by oleic, linolic, and linolenic acids

Detergents of various types have also

(Stock and Francis, 1940, Klein and Stev

however, think these agents to be suffic

ivory soap in a 1 per cent solution killed virus, but 15 minutes or more was needed

Soap solution quickly destroys virus spread on the palm of the hand (Parker and MacNeal, 1944).

CHEMOTHERAPY

The following agents also have been found devoid of protective effect *in vivo*. acridines, guanyl compounds, alkaloids, arsenicals, antimonials, gold compounds, oils, salicylates, peroxides, formaldehyde compounds, nitro compounds, dyes, and miscellaneous chemicals (Andrewes, King, and van den Ende, 1943, see also *U.S. Nav Med Lab*, 1943 *a*, Cutting *et al*, 1947).

Quinine administered in the diet had a slight but consistent retarding effect on the course of infection in mice (Seeler, Graessler, and Ott, 1946).

Various antibiotics have been found valueless in the treatment of experimental influenzal infection penicillin, tyrothricin, tyrocidin, gramicidin, streptomycin (*U.S Nav. Med Lab 1943 a, Florman, Weiss, and Council, 1046, Cutting et al*, 1947)

Streptomycin appears to have no inhibitory effect on the growth of virus A and B in the allantoic sac (Lowell and Buckinham, 1946).

Ultraviolet irradiation has been extensively studied. With the lamp used virus in allantoic fluid withstood about 60 minutes exposure, but after dialysis, infectivity was lost in about 30 seconds (Henle and Henle, 1944*a*, 1947). McLean *et al* (1945 *d*) investigated the reaction of purified swine virus. Tables showing the rate of fall in titer in irradiated specimens are available (Henle and Henle, 1946*b*). A wavelength of about 2650 Å appears to be the most destructive (Hollaender and Oliphant, 1944).

The effect of irradiation on the various properties of influenza virus will be found in the appropriate sections. In this connection, Henle and Henle (1947) have carried out a detailed study, and have shown that the biological properties are lost in the following order (1) Ability to propagate (2) Toxicity. (3) Interfering property in the chick embryo, and the inhibitory effect on embryonic development. (4) Hemagglutinating capacity, including adsorption-elution, the ability to render red cells refractory to agglutination by fresh virus, and adsorption on to cells of the allantoic sac. (5) CF activity is partly destroyed together with the HA (600 S component), and is partly more resistant (possibly 30 S).

They have shown that 4 distinct preparations can be obtained. (1) After irradiation for 1–2 hours, the preparation agglutinates red cells and renders them inagglutinable This preparation is adsorbed onto cells of the allantoic sac, but causes no visible changes. (2) After irradiation for 3–5 minutes, the fluid behaves similarly, but in addition alters the cells of the allantoic sac, so that they become insusceptible to infection by active virus (3) After exposure for ½–1 minute, the preparation is, in addition, toxic. (4) Nonirradiated virus multiplies in the allantoic sac.

SURVIVAL AND DESTRUCTION OF ATOMIZED VIRUS IN AIR

A number of experiments has been carried out in which virus has been atomized in the form of a mist in special chambers, or even small rooms, and its survival tested by exposing mice, these animals can be infected readily by inhalation Thus Wells and Brown (1936) found that virus could be recovered from air after 30 minutes

Virus survived much longer in dry atmospheres, and at relative humidity 17–24 per cent it remained infective for 24 hours (Loosli *et al*, 1943) A dried virus mist was found to be more resistant to the destructive action of iodine vapor than a moister one (Stone and Burnet, 1945)

Virus suspended in air in the form of atomized droplets can be destroyed (so as not to infect exposed mice) by ultraviolet light (Wells and Brown, 1936, Wells and Henle, 1941, Stokes and Henle, 1942) Edward, Lush, and Bourdillon (1943) found light of wavelength 2537 Å highly effective

The atomization of various antiseptic substances also destroys infective droplets of influenza virus propylene glycol (Henle and Zellat, 1941, Stokes and Henle, 1942), iodine (0 1 p p m, Stone and Burnet, 1945). Sodium hypochlorite (1 per cent) destroyed 90 per cent of atomized virus A in a quarter of an hour, and hypochlorous acid gas, 1 volume in 2 million volumes of air, was probably even more effective (Edward and Lidwell, 1943)

The infectivity of virus A was completely destroyed by exposure to the vapors of α or β naphthyl isocyanate, phenyl isocyanate, and p-nitrobenzoyl chloride, oxyquinoline, thio-urea, oil of nutmeg, and oil of mustard showed slight activity (Grubb, Miesse, and Puetzer, 1947).

CHEMICAL AGENTS

A considerable number of chemical substances has been tested for their inactivating effect on virus *in vitro* Formalin is perhaps the most widely used In a strength of 0 08 per cent, virus is destroyed in 8 days (McLean *et al*, 1945 *d*)

The following tables show the results of tests with numerous other substances

TABLE 26

Soap solution quickly destroys virus spread on the palm of the hand (Parker and MacNeal, 1944).

CHEMOTHERAPY

Despite a preliminary suggestion that sulfonamides might have some beneficial effect on mice infected with influenza (Climenko, Crossley, and Northey, 1939), it is not now believed that they have any protective action (Coggeshall and Maier, 1942, Andrewes, King, and van den Ende, 1943, *U.S Nav. Med. Lab*, 1943 *a*; Harford, Smith, and Wood, 1946, Cutting *et al*, 1947).

The following agents also have been found devoid of protective effect *in vivo*· acridines, guanyl compounds, alkaloids, arsenicals, antimonials, gold compounds, oils, salicylates, peroxides, formaldehyde compounds, nitro compounds, dyes, and miscellaneous chemicals (Andrewes, King, and van den Ende, 1943, see also *U.S Nav Med Lab.*, 1943 *a*, Cutting *et al*, 1947).

Quinine administered in the diet had a slight but consistent retarding effect on the course of infection in mice (Seeler, Graessler, and Ott, 1946).

Various antibiotics have been found valueless in the treatment of experimental influenzal infection penicillin, tyrothricin, tyrocidin, gramicidin, streptomycin (*U S Nav Med Lab* 1943 *a*, Florman, Weiss, and Council, 1946, Cutting *et al*, 1947).

Streptomycin appears to have no inhibitory effect on the growth of virus A and B in the allantoic sac (Lowell and Buckinham, 1946)

It has been reported that nitroakridin 3582 has an inhibitory effect on the growth of influenza virus B in the allantoic sac (Green, Rusmussen, and Smadel, 1946), and McClelland has confirmed this point in these laboratories; hexamidine (4,4′ diamidino diphenoxy hexane di-isethionate) has a similar effect (McClelland and van Rooyen, 1948).

Apple pectin injected in the allantoic sac shortly before or after virus was found to inhibit virus multiplication, gum acacia showed a similar but less pronounced action (Green and Wooley, 1947).

Rubin and Giarman (1947) showed that various antibiotic lactones and analo-
...butyrolactone; 6-methoxy-8-(2,5-
...4-olide; 3-methyl-5-carboxy-2-

INFLUENCE OF BUFFERS AND pH

Knight (1944 *a*) investigated the effect of various buffers on the stability of centrifugally purified PR8 virus at pH 7. Borate, veronal, and phosphate buffers, at a concentration of about 0.1 M, maintained activity at 4° C. for several weeks. The phosphate buffer is probably the most practical. Unbuffered saline was found to be a poor solvent for preserving activity, irrespective of pH.

Miller (1944 *b*) has investigated the influence of pH on the infectivity of various virus strains at a protein concentration of 0.1 mgm. per c.c. in phosphate buffer. Infectivity of PR8 was most stable at pH 6.5–7, swine virus at pH 7–7.9, and Lee virus at 7.9 or higher. Under suitable conditions of buffer and pH, infectivity decreased while chick cell agglutinating activity remained unaltered; the rate of loss of infectivity was greater than the
When tests of stability were performed in a
strains showed less marked differences, and
agglutinating activity and infectivity than when stored at the same concentration in phosphate buffer. Under these conditions, the Lee and swine strains possessed maximum stabilities of agglutinating activity and infectivity at pH 7–8, while the infectivity of PR8 was more stable at pH 7 than 8. In detailed experiments with Lee virus it was found that infectivity and agglutinating activity were maintained best in the composite phosphate-glycine-NaCl buffer.

With PR8, activity was found to be much more stable at 4° C. than 23° C. When stored at concentrations of 2 mgm. per c.c. at 4° C. in phosphate buffer at pH7, the PR8 and Lee strains were much more stable than when stored at 0.1 mgm. per c.c. There was no significant loss over 2 months.

BIOLOGICAL AGENCIES

The Skin

Estimates of the time in which virus A and B is inactivated on the human skin vary from 10 minutes (*U.S. Nav. Med. Lab.* 1942 *b*), to over 45 minutes (Parker and MacNeal, 1944). The presence of saliva does not inhibit the destructive action of skin on dried virus (*U.S. Nav. Med. Lab.* 1943 *d*).

Virus Inactivating Power of Human Nasal Secretions

Burnet and his colleagues have shown that the serous secretion from the normal nasal passage has the property of inactivating influenza virus. The secretion is obtained by pushing a roll of gauze or cotton wool up the nostril. The material soon becomes soaked with secretion, and is wrung out with artery forceps to yield about 1 c.c. of clear fluid. Af ... rilized by heating to 56° C. for ½ hour, or by ... ane. The properties of the virus inactivating ... , Lush, and Jackson, 1939, Burnet and Lush, 1940 *b*, Francis, 1940 *a*)

1. It has been shown to inactivate various strains of virus A and the swine strain. It also inhibits CCA by virus (Soloviev and Parnes, 1946).

2. The inactivating effect proceeds slowly, and the degree of inactivation increases progressively as contact is maintained at 36° C; there is practically no effect at 0° C.

3. There is no evidence that virus inactivated by VIA can be reactivated by dilution

4. The effect of VIA is destroyed by boiling for 10 minutes, or 70–75° C. for 20 minutes

5 There is no correlation between lysozyme activity and VIA.

6. VIA is not a bile salt.

7. The capacity of the human nasal secretion to neutralize virus is not significantly influenced by deficiency of vitamins A or C, followed by "flooding" with the substances (Feller *et al.*, 1942).

8. Although there is no close parallel between VIA and the antibody titer of the serum, the majority of those with a low titer have no VIA, and *vice versa* most of
gests th
Soloviev
parallel

9 Francis and Brightman (1941) found that in 9/10 persons a natural infection with type A virus was followed by the development of a sharp increase in the capacity of their nasal secretion to inactivate virus Although not parallel, increases of neutralizing antibody in the serum were also observed.

10. As further confirmatory evidence that VIA is derived from serum antibody, it has been shown that persons given live virus in one dose subcutaneously develop a rise in serum antibodies and a concomitant enhancement of VIA; 2 inactivated vaccines produced similar effects (Francis *et al*, 1943).

Virus Inactivating Power of Animal Secretions

Immunization of rabbits has been shown to be accompanied by a rise in the virus neutralizing power of the nasal secretion, rising parallel with serum antibody (Soloviev and Parnes, 1946) These authors found no evidence that VIA was produced locally in the nasal cavities.

These observations lend still further weight to the belief that VIA is actually derived from serum antibody.

CHAPTER LXI

HEMAGGLUTINATION BY INFLUENZA VIRUS

PREPARATIONS containing any strain of influenza virus have the property of causing agglutination of chick and other varieties of red cell, as first shown independently by Hirst (1941)[1] and McClelland and Hare (1941).

Thus, Hirst found that if the red cells of an infected embryo gain access to allantoic fluid, agglutination takes place. When allantoic fluid is mixed in a test tube with washed adult chick cells, agglutination occurs, and the red cells sediment quickly to form a ragged granular pattern on the rounded bottom of the tube. Allantoic fluid, he found, may agglutinate even when diluted 1/512. This test is usually known as the chick red cell agglutination (or CCA) test, although other [illegible] that influenzal antibody specifically [illegible] and that antisera can be titrated by [illegible] red cell agglutination inhibition (or CCA-inhibition) test.

McClelland and Hare in their independent observations found that the red cells from a number of species are agglutinated by virus A and B, and that the virus is adsorbed to the red cell. The hemagglutinin can be destroyed by heat. They found a fair correlation between antibody titrations carried out by the CCA-inhibition and mouse tests.

These original observations have been abundantly confirmed, and extended, by Hirst, McClelland, Hare, their colleagues, and many independent observers. Burnet, in his study of the O-D phenomenon, and in other work, has made many interesting observations. The discovery of the Hirst-McClelland-Hare phenomenon of chick cell agglutination has led directly to a very considerable and rapid increase in our knowledge of the properties of influenza and other viruses, and has greatly simplified observations on immunity in natural and experimental infections.

SOURCES OF INFLUENZA HEMAGGLUTININ

Influenza hemagglutinin is most easily detected in allantoic or amniotic fluids from infected eggs. It can be found also in suspensions of infected chick embryo lung, as has been particularly shown by Burnet in his study of the O-D phase phenomenon. It can also be found in suspensions of mouse or ferret lung. Purified preparations of influenza virus, for example those obtained by centrifugation from allantoic fluid, can be standardized on the basis of their CCA potency per mgm. of nitrogen. Nasopharyngeal washings may agglutinate chick cells, and this can be inhibited by serum (Soloviev, Shubladze, and Meltzer, 1945).

SPECIES OF RED CELL AGGLUTINATED

The following are the reactions observed when preparations of influenza virus are mixed with the red cells of the most readily accessible species (McClelland and Hare, 1941, Burnet and colleagues, Twyble and Mason, 1944, Shubladze and Soloviev, 1945)

agglutination occurs—

chick (embryo, day-old, or adult), duck, pigeon, turkey, guinea-pig, human, dog, mouse, and ferret (weak),

[1] *References are appended at the conclusion of Ch. LXIII, p. 671 et seq.*

no agglutination occurs—

rabbit, rat, horse, sheep, fox, cat, and frog

Slight differences may occur using embryonic chick cells as distinct from adult cells, in experiments where cells are treated with virus and then exposed to the action of other viruses (Burnet *et al*, 1945, see below).

It will be remembered that Burnet claims that virus as originally isolated from the patient (O phase) does not readily agglutinate fowl cells, but agglutinates guinea-pig, human, or pigeon cells. Virus in its usual passage form (D phase) agglutinates chick and other red cells readily.

The most complete single series of observations is that of Clark and Nagler (1943) who obtained the results shown in Table 27 (to save repetition the reactions with 2 other viruses are also shown). They stress that this table gives a broad picture, and that some of the agglutinations are weak It will be observed that they find a difference in the agglutinating capacity of influenza virus strains, and also record as agglutinable some cells described as inagglutinable by others.

PROPERTIES OF THE INFLUENZA HEMAGGLUTININ

Influence of Various Physical and Chemical Factors

Heat.

Hemagglutinin is destroyed by heat (60° C), but it is possible to expose virus to a lower degree of heat so that infectivity is lost before hemagglutinating capacity (Hirst, 1942 *c*, *d*) McKee and Hale (1946) found that concentrated virus heated to 57° C for 70 minutes was noninfective, but still possessed some agglutinating capacity. Lauffer and Carnelly (1945) have made a mathematical study of the process of inactivation of hemagglutinin by heat (61° C.). When the logarithms of residual agglutinating activities were plotted against times of heating, in the majority of cases one could not fit a straight line to the data. However, when the reciprocals of the square roots of the residual concentrations were plotted against the times, straight lines could generally be fitted. This relationship held for the

first 90–99 per cent. of the course of the reaction, but many cases of deviation were observed. After discussing various possible explanations of this behavior, the authors suggested that the virus particles (i.e., hemagglutinins) are inhomogeneous *with respect to the ease with which hemagglutinin is destroyed.* It has been found with other viruses that the rates of inactivation and denaturation vary inversely with concentration. The effect of initial virus concentration on specific reaction rates applied equally to the thermal destruction of influenza hemagglutinin.

It now appears that strains of virus may differ from one another in the stability of their CCA activity, and that the method of maintenance by passage is also of importance. Thus, Salk (1946 *a*) found that the Lee hemagglutinins withstood 61.5° C. for 90 minutes without a drop in CCA titer. The hemagglutinins of other strains tested were quickly destroyed at this temperature; strains differed one from another in this respect; lines of a single strain maintained in different hosts showed varying degrees of stability to heat, apparently due to an inherited property.

Francis (1947 *a*) found that 56° C. for 30 minutes did not alter the CCA titer of a number of B strains in allantoic fluid, although in 2 cases the titer was lowered. When the same strains maintained in mouse lung were heated similarly, their CCA activity was completely or markedly inactivated. Francis also found that this temperature did destroy the hemagglutinating capacity of several A strains, in distinction to his findings with B strains.

Storage.

On prolonged storage in the refrigerator, allantoic fluid may become noninfective, yet still cause agglutination of chick cells (Hirst, 1942 *c*). When stored at 37° C., infectivity is lost in a few days, but hemagglutinating activity remains for months (Pearson, 1944 *a*).

Stanley (1945 *b*) studied the effect of freezing formolized purified virus, and found that CCA activity was immediately lost. Drying from the frozen state resulted in loss of CCA activity.

Chemical and physical agents.

Preparations of formolized purified influenza virus as used in vaccines still cause hemagglutination, although they are of course noninfective. Salk (1946 *b*) found that formalin increased the heat stability of the hemagglutinins of a number of A and B strains, strains varying one from another in this respect. The hemagglutinins of 3 different lines of the Lee virus were, however, deleteriously affected in their heat stability by formalin. Excess formalin destroys CCA activity (Stanley, 1945 *b*). Virus rendered noninfective by mustard was found still to agglutinate red cells (Rose and Gellhorn, 1947).

When allantoic fluid is exposed to irradiation, infectivity is first destroyed, then the interfering power is lost, and finally the hemagglutinating capacity is lost on prolonged exposure (Henle and Henle, 1945 *d*). In more detailed experiments (1947) they reported that the HA titer of PR8 was unaltered for about 60 minutes of irradiation, loss of activity occurred rather rapidly at some time during the second hour. The HA of the Lee strain was more resistant, and survived for 2–4 hours, during the first 2 hours, the titer actually increased.

Hemagglutinin is not destroyed by bacterial contamination in egg fluids or organ suspensions.

The hemagglutinin of the Melbourne strain is resistant to the alpha toxin of *Cl welchii*, and to cobra venom, although vaccinia hemagglutinin is inactivated (Stone, 1946).

Miller (1944 *b*) has investigated the effect of pH in various buffer solutions on CCA activity and infectivity. He found that both properties are lost more rapidly on the acid than the alkaline side of the optimum pH. Under suitable conditions, infectivity decreases while the red cell agglutinating potency remains unaltered.

Both infectivity and CCA activity are removed together by filtration through a Seitz or Berkefeld filter (Twyble and Mason, 1944).

The Interaction between Virus and Red Cells

Influenza virus is adsorbed to red cells that it agglutinates, and can be later eluted therefrom, showing that the cell-virus union is reversible. Adsorption of virus to, and elution from, red cells has been used as a method of purifying virus (see p. 613), and of obtaining pure O phase virus (see p 595) The stages in this reaction are as follows

rbed to chick red cells from a virus-contain- the quicker and more complete is the ad- of virus adsorbed rapidly decreases when the cell concentration is below 1 per cent, with a 2 per cent. suspension, adsorption is virtually complete (Hare, Curl, and McClelland, 1946)

2. With PR8, hemagglutinins are adsorbed at 4° C. rapidly and almost completely. With increase in temperature, the adsorption is less complete, although taking place more rapidly. At 4° C. maximum adsorption occurs in 5 hours, at 27° C. in 5 minutes, and at 37° C. in 3–5 minutes (Hirst, 1942 *d*).

3. The activity of the portion of the cell responsible for the adsorption is not destroyed, although somewhat reduced, by heating to 100° C. for 5 minutes, adsorption occurs to the stroma of the cell (McClelland and Hare, 1941; Hirst, 1942 *d*) Apparently the nucleus of chick cells can also adsorb virus (Parodi, Lajmanovich, and Mittelman, 1944).

4 When fowl cells agglutinated by influenza virus, and left standing at room temperature for an hour or so, are shaken, they usually reagglutinate. A stable suspension of such virus-treated cells can be obtained by treating with specific homologous antiserum and washing in saline, presumably the serum combines preferentially with the virus and "frees" it from the red cell (Burnet, 1945, Burnet *et al*, 1945). Stabilization can also be obtained by allowing agglutination to occur at 37° C, and shaking the tube periodically. Eventually the cells become stable and linear scale (see below) cells without the use of

5. After a varying period, the adsorbed hemagglutinin elutes from the cell. The larger the amount of red cell suspension used to adsorb, the less the speed and extent of subsequent elution. The degree of elution at 4° C. is negligible in 18 hours, but increases as temperature rises. Almost all the adsorbed hemagglutinins are released in 4–6 hours at 23° C. with the Lee strain, and at 37° C. with PR8. The Lee strain is adsorbed and eluted more quickly than PR8 (Hirst, 1942 *d*) Within limits, variation in the volume of the eluent does not affect the yield of virus, although, of course, altering the titer of the fluid (Hare, Curl, and McClelland, 1946).

6 After red cells have fully adsorbed and eluted agglutinin, they cannot adsorb any further agglutinin, nor can such cells be agglutinated by fresh virus preparations of the same strain (Hirst, 1942 *d*) Presumably, the cell receptors in the erythrocyte responsible for adsorption of virus and consequent agglutination are altered in some way, even after elution, so that they can no longer adsorb fresh virus. Such cells may be fully agglutinable by other strains of virus.

By treating red cells with various strains, Burnet, McCrea, and Stone (1946) order, such that when a cell virus it is not agglutinated by following it. The order of viruses causing hemagglutination is as follows mumps, Newcastle virus, Melb, Mil A O, WS, Bel O, Ian O, Mil A D, Lee, Bel D, Ian D, swine, Hut B, and Mil B. The term "receptor gradient" of the red cell is used in this connection (see

also Burnet, 1945; Burnet *et al*, 1945). For example, red cells treated with Newcastle virus cannot be agglutinated by this agent, but are susceptible to agglutination by influenza strains.

7. Further evidence supporting the existence of these red cells receptors has been furnished by Friedewald, Miller, and Whatley (1947) whose work is described in detail on p. 638. They were able to obtain an extract from chick red cells that inhibits agglutination. When these extracts were made from red cells that had fully adsorbed and eluted virus (removal of receptors), no inhibition of agglutination could be demonstrated. It looked as if the inhibiting factor was identical with the receptor for virus hemagglutinin.

8. Virus-treated red cells become agglutinable by normal sera, very few human sera failing to agglutinate cells treated with swine virus to a titer of 160, guinea-pig and rabbit sera give a lower titer, the titer obtained with normal sera is roughly proportional to the position in the receptor gradient series of the virus used to prepare the cells (Burnet, McCrea, and Stone, 1946, Chu and Coombs, 1947). In general, the titer given by a normal serum is low for viruses early in the series and higher for those later. This is thought to be an example of the panagglutination of Thomsen.

9 The agglutinins can be adsorbed to, and eluted from successive batches of red cell, without any appreciable loss of CCA activity; the virus particles do not appear to be altered by their contact with the red cells (Hirst, 1942 *d*) Hirst has also studied the adsorption of influenza virus to living cells of the respiratory system (see p. 601).

10. Inactivated virus particles can be adsorbed and eluted (Hirst, 1942 *d*) Irradiated particles can also be adsorbed and eluted as long as the HA is not totally destroyed (Henle and Henle, 1945 *d*, 1947); cells treated with particles of this nature are refractory to agglutination by influenza and mumps viruses (1947)

11. The infective agent in virus suspensions is adsorbed simultaneously with the hemagglutinin, and 95 per cent of infectivity is removed in 15 minutes Thereafter the infective agent is gradually released from the cells, and after 4 hours the 50 per cent. mortality titer of the supernatant fluid is as high as at the beginning of the experiment (Hirst, 1942 *d*)

Effect of Bacterial Enzyme Products on Red Cell Receptors

The toxin of *Cl. welchii* Type A was found to render red cells (human) inagglutinable by influenza viruses. As contact continued, the red cell receptors were removed in roughly the order of the red cell gradient described above, i.e., after ½ hour of contact most strains were still able to agglutinate the red cells, after 3 hours only strains towards the right hand end of the scale were able to do so, and this effect was more marked after 6 hours (Burnet, McCrea, and Stone, 1946). These authors found that filtrates of the cholera *vibrio* had the same effect The susceptibility of the cells to agglutination by different viruses was progressively lost in almost the same sequence as resulted from virus action The only outstanding discrepancy was the undue retention of susceptibility to agglutination by mumps virus

This work rendered it highly probable that the action of influenza viruses on red cell receptors was also due to similar enzymes or "enzymatically active groupings" on the surface of the virus particle

Observations with Anti-Rh Sera

Chu and Coombes (1947) treated human cells with NDV and influenza strains, and then exposed the stabilized suspensions to antiserum containing the "incomplete" anti-D Rh antibody Only the Rh positive treated cells containing the D Rh antigen were agglutinated There was a gradation of activity, NDV being the strongest, and swine, Lee, and PR8 following These workers concluded that

viruses exert 3 sets of action on red cells (1) red cell receptors are removed, (2) panagglutinability is produced, (3) appropriate cells are rendered susceptible to agglutination by incomplete Rh antibody. As shown by Burnet, McCrea, and Stone (1946), and just mentioned, cholera vibrio filtrate has the same effect (see also Pickles, 1946).

The Relationship of CCA Activity to Infectivity and Other Properties

From what has been said, it will be evident that although the properties of infectivity and CCA potency of a preparation are usually closely related, they can be separated. For it is possible to destroy infectivity, for example, by heat, storage, irradiation, or formalin, and yet leave a preparation with practically unimpaired CCA activity.

Hirst (1942 *c*) showed that the CCA titer and mouse infectivity titer of a given strain are closely correlated in fresh, or carefully stored, preparations The CCA titers of increasing dilutions fall parallel to the mouse infectivity titers, when any given strain is titrated by the 2 methods If different strains are compared, the CCA titer by itself gives no indication of the likely infectivity. Hirst found that 4 strains in allantoic fluid had approximately the same CCA titer, but were of quite different virulence for mice.

There is no doubt that hemagglutination is brought about by the elementary bodies—the infective particles—of influenza virus, and not by any other fraction of the virus Centrifugation studies have shown that CCA activity is associated with the 600 S component and not with 30 S It will be remembered that the 600 S component is associated also with infectivity, and immunizing ability (see Ch. LVI) The interfering property of influenza virus is also associated with the elementary body (see p 621).

The application of heat to concentrated virus was found to cause a marked drop in hemagglutinating activity, but the ability of the inactivated virus to bind antibody was not lessened to the same extent (McKee and Hale, 1946)

When exposed to ultraviolet light, the HA is destroyed after infectivity, toxicity, and interfering capacity, but some complement fixing power remains when HA is destroyed (Henle and Henle, 1947).

CHICK CELL AGGLUTINATION INHIBITION

Antisera containing influenzal antibody inhibit chick cell agglutination (Hirst, 1941, McClelland and Hare, 1941) This inhibition is specific, and antiserum to virus A does not inhibit agglutination caused by virus B It appears that the inhibiting antibody is associated with the gamma component (Wyckoff and Rhian, 1945).

Burnet *et al* (1945) have studied the academic aspects of CCA inhibition They found that (*a*) the law of constant proportions holds over a wide range of concentrations, (*b*) a "time" effect can be clearly shown with highly diluted reagents, (*c*) equilibrium can be reached even in the presence of red cells They concluded that the reaction conforms to the general character of virus-antibody reactions Presumably virus and antibody combine, so that no free virus is available to agglutinate the red cells

The procedure adopted is to set up a series of test tubes containing a fixed quantity of known [illegible] ilutions of the serum under test. If the [illegible] tination will be inhibited in a varying [illegible] 50 per cent. agglutination is regarded as expressing the titer of the serum

The serum of ferrets, hamsters, and mice recovered from infection contains

CCA inhibiting antibodies, and these can also be stimulated by the intraperitoneal inoculation of allantoic fluid.

As influenza is so prevalent, the majority of "normal" human sera agglutinates chick cells to a low titer. On recovery from influenza, there is in most cases a marked production of antibody, so that the titer becomes several times higher than it was in the acute phase. The question of the correlation between the antibody titers found by various methods is discussed in Ch. LXI.

NONSPECIFIC AGGLUTINATION INHIBITION

Nonspecific inhibition of agglutination may occur under various circumstances, of which at least 5 have so far been identified. (1) the presence of a heat-labile factor in normal serum, (2) certain peculiarities of individual red cells, (3) the action of a possible heat-labile component in the virus particle normally preventing inhibition brought about by serum, (4) the action of polysaccharides, (5) the effect of red cell and tissue extracts

1. Normal human and animal sera may contain a factor, destroyed at 56° C in 30 minutes, which in low dilutions inhibits the agglutination of chick red cells by viruses A or B, thus mimicking the effect of specific antibody (Hirst, 1942 c, Beveridge and Lind, 1946).

Burnet and McCrea (1947) in experiments on O and D phases, found that normal ferret sera showed very high nonspecific inhibitory titers.

Certain of these normal sera inactivated O and D phase Bel. virus when inoculated in the amniotic or allantoic cavities respectively. Melbourne virus was not inactivated. Tests showed that both normal and immune inhibitors are probably present in the gamma globulin fraction The normal inhibitor of Bel (D phase) hemagglutination was precipitated at a slighter lower salt concentration than the inhibitor for strain Melbourne. The power to inhibit Melbourne hemagglutination was completely lost within 20 minutes on heating ferret serum to 62° C The inhibitory power against Bel. was much more resistant, and the inhibitory factor behaved very like immune body

This high inhibitory power of normal ferret serum against hemagglutination by the strain Bel. was not due to previous infection The experiments indicated a possible source of error in the interpretation of serological reactions with influenza viruses, and provided a new example of pseudo-immunological activity of a normal serum component. It was suggested that a proportion of serum globulin molecules appear to possess surface configurations reacting with "receptors" on red cells and virus particles.

McCrea (1947) showed that nonspecific inhibition of hemagglutination could be demonstrated in tests with strain Bel (D phase) and normal rabbit serum to titers of 100–320. He described a simple heat treatment which rapidly destroys the nonspecific hemagglutination inhibitor in rabbit serum, leaving the true immune inhibitor relatively unchanged Heating normal rabbit serum for 15–20 minutes at 62° C usually resulted in complete loss of nonspecific inhibitory properties The inhibitory activity fell off logarithmically with time The temperature coefficient was 2.2 for a 4° C. rise

The destruction rate of the specific inhibitory factor in immune serum was of a different order. At the time when the nonspecific inhibitory titer was completely destroyed, 75 per cent of the immune titer remained, and thereafter fell more slowly, 30–50 per cent of the original serum titer remained after heating at 62° C for 3 hours Fractionation experiments showed that both specific and nonspecific inhibitors were recoverable in the globulin fraction The inhibitory activity appeared associated with the gamma globulins.

It is of particular interest that a normal serum can behave in some respects like virus antiserum, and that this behavior is due to the normal serum gamma globulin It appears that the surface configuration of normal rabbit globulin resembles the

configuration of immune globulin (against the particular strain of virus used) sufficiently to give a pseudospecific interaction with the virus antigen. However, there are well-defined differences in heat stability. The thermal destruction of inhibitory activity in normal rabbit serum is accompanied by denaturation of the globulin, and complex formation between the denatured globulin and albumen.

2. Burnet and Stone (1946) found sharp differences between fowl cells from different birds in regard to the inhibitory titer of a heated serum containing no influenzal antibody. Only cells from 15 per cent of fowls were capable of demonstrating antibody titers below 10 with two B strains Later it was reported that for determination of antibody titers, the red cells should be obtained from fowls specially selected as yielding highly susceptible cells, a wide range of apparent inhibition titers was obtained with different cells using a human serum containing no antibody, but there was less variation in titer using a high titer serum (Ander-

olated B strains to be very susceptible

The same phenomenon was recorded

Francis has made important observations in this connection It was first shown that freshly isolated strains of B virus, in allantoic fluid, when used as antigen in CCA inhibition tests with normal serum gave very high antibody titers, approaching those observed with immune serum (Francis, Salk, and Brace, 1946). This inhibitory effect on agglutination was lost with most strains on passage by the allantoic route.

In later studies, Francis (1947 *a*) investigated the effect of heat (56° C. for 30 minutes) on the CCA activity of B strains, in general this had no effect on the CCA titer. However, when heated and unheated aliquots were used as antigens in CCA-inhibition tests with inactivated sera, a sharp disparity was observed.

The unheated virus antigen gave antibody titers for normal sera ranging from 0–64, and for immune sera from 128–1024 The heated antigen, with the same normal sera, gave apparent titers of 128–2048 The increases in titer in the immune sera detected by heated antigen were not in proportion

Francis postulated that influenza

stable and -labile components The

and reacts with specific antibody to

The heat-labile component reacts with, and neutralizes the effect of, a component of normal serum that tends to inhibit hemagglutination by virus In the presence of the intact complex in unheated virus, especially after a few allantoic transfers, the natural serum factor is countered by the labile component, and specific antibody can be measured If the labile component is absent, as in freshly isolated material, or after heating, the normal serum factor prevents agglutination and obscures the measurement of specific antibody

An enzyme produced by *V. cholerae*, that has been shown to parallel the action of virus on red cells in removing "receptors," also destroys Francis' normal serum

this inhibitor was

inhibitors mucus

he activity of the

ved by incubation

nhibitory effect of

polysaccharides.

4. Thus, the following have been shown to exert a considerable effect in inhibiting hemagglutination *in vitro:* flaxseed mucilage, citrus and apple pectins, blood group A substance, gum acacia, and gum myrrh (Green and Worley, 1947) Apple pectin has been found also to inhibit virus multiplication (see p. 628)

Inhibition by Red Cell and Tissue Extracts

5. A number of observations has been made on the inhibiting effect of red cell and tissue extrac· ... Thus, it has been found that extracts of red cells t ... virus may inhibit agglutination, presumably by ... intact red cell receptor; on prolonged contact of virus and inhibitor, the latter is progressively inactivated (Bovarnick and de Burgh, 1947; Green and Worley, 1947). Friedewald, Miller, and Whatley (1947) have carried out important studies in this respect.

(*a*) Inhibition of hemagglutination produced by the influenza (and mumps) virus was obtained in high titer with serum and tissue extracts of various human oragns (lung, liver, kidney, spleen), and organ titers were usually higher than serum titers. Heating to 75° C. for 30 minutes had no significant effect on the inhibiting substance in serum. In general, the titers of tissue extracts were reduced by heating to 65° C It seemed reasonable to conclude that at least part of the inhibition shown by serum and extracts of human tissues was due to a factor other than specific antibody.

(*b*) Comparable results were found with normal rabbit and guinea-pig tissues.

(*c*) Preparations of perfused organs were still inhibitory, but were usually reduced in activity two- to fourfold, suggesting that hemaglobin as well as tissue cells contained the inhibitory substance.

(*d*) Extracts of human, chicken, sheep, and rabbit red cells were prepared by mechanical disruption The supernatants were tested for capacity to inhibit agglutination of chick cells by influenza (and mumps) virus The findings clearly indicated a correlation between the capacity of the red cells to agglutinate with these viruses, and the inhibition titers produced by extracts of red cells. Thus, human ar ... extracts of these c ... poorly with the ... varied

(*e*) Extracts of human and chick cells did not neutralize the infectivity of influenza viruses, and did not fix complement.

(*f*) The substance in human cells responsible for inhibition was distinct from the A and B substances and the Rh factor

(*g*) The inhibitory agent in human and chicken cells was destroyed by heating at 65° C for 30 minutes

(*h*) Chicken red cells were treated with influenza virus at 37° C till they no longer agglutinated, having adsorbed and fully eluted virus Extracts of these cells did not cause detectable inhibition of agglutination It is thus seen that removal of receptors from red cells also removed the factor inhibiting red cell agglutination

(*i*) The simple explanation of nonspecific inhibition of virus hemagglutination is that the receptor substance released from red cells combines with virus and blocks the union of virus with red cells

There is no simple method available for differentiating nonspecific inhibition from that produced by specific antibody A rise in the serum inhibition titer, however, is undoubtedly due to specific antibody

(*j*) It appears that normal allantoic fluid has an inhibiting effect on virus hemagglutination (Svedmyr, 1946)

THE SIGNIFICANCE AND EXPLANATION OF VIRUS HEMAGGLUTINATION

A number of viruses causes hemagglutination, and these can be grouped as follows (Clark and Nagler, 1943, Burnet, 1945, Burnet *et al*, 1945, Burnet, McCrea, and Stone, 1946)

... The members of this group

hemagglutinins of influenza virus are identical with the virus particles, and can be eluted from agglutinated cells. Cells treated with mumps and Newcastle viruses are agglutinated by immune serum

It is suggested that the viruses in this group become attached to a single series of receptors which vary in their accessibility and the ease with which they can be removed by virus action, the two qualities are directly correlated. There is no suggestion of there being specific receptors for each virus (Burnet, 1945; Burnet *et al*, 1945).

Cl welchii Type A toxin, and filtrates of *V. cholerae*, both enzymes, change the surface character of human red cells so that they become progressively less sensitive to agglutination by viruses of this group The virus receptors are removed in almost the order of the receptor gradient (Burnet, McCrea, and Stone, 1946). Although there are certain differences between the activity of bacterial enzymes and the action of influenza viruses, it seems probable that agglutination by viruses of this group is brought about by enzyme-like agents. On the strength of finding

or by the enzyme of *V. cholerae* that has similar receptor destroying properties. It appears that influenza virus possesses an enzyme acting on glandular type mucin

2. *Variola-vaccinia-ectromelia* (see Ch. XXXI). These hemagglutinins can be readily separated from the EB's, and appear to be some product of the virus Cells which are susceptible to the action of viruses in this group are also agglutinated by suspensions of tissue lipoids This type of hemagglutinin cannot be eluted from the agglutinated cell

3 *Mouse pneumonia virus* (PVM, see Ch LXVIII).

4 *Fowl plague virus* (Lush, 1943)

TECHNICAL CONSIDERATIONS IN CCA AND CCA-INHIBITION TESTS

Before describing the technique to be followed in CCA and inhibition tests, to save repetition, a number of technical points must be considered

Red Cell Suspensions

Although many species of animal furnish red cells susceptible to the agglutinins of influenza virus, those of the fowl are usually used, and for most purposes are sufficiently reliable There is, however, a definite variation in susceptibility to agglutination of suspensions from different birds, and even of the same bird at different seasons (Stuart-Harris, 1943). When a large number of tests are being performed at once, the same batch of red cells should be used throughout To obviate this factor of varying agglutinability of red cells, Miller and Stanley (1944) recommend the parallel titration of an antigen of standard potency (see below).

with B strains Burnet om different fowls in luenza antibody, only titers below 10 with the particular B strains used.

The agglutinating titer of a virus preparation varies inversely with the concentration of red cells, i e, the stronger the cell suspension, the lower appears the titer of CCA activity According to Salk (1944), 0 5 c c. of a 0 25 per cent suspension

Inhibition by Red Cell and Tissue Extracts

5. A number of observations has been made on the inhibiting effect of red cell and tissue extra ... Thus, it has been found that extracts of red cells ... virus may inhibit agglutination, presumably by ... intact red cell receptor, on prolonged contact ... is progressively inactivated (Bovarnick and de Burgh, 1947, Green and Worley, 1947) Friedewald, Miller, and Whatley (1947) have carried out important studies in this respect.

(*a*) Inhibition of hemagglutination produced by the influenza (and mumps) virus was obtained in high titer with serum and tissue extracts of various human oragns (lung, liver, kidney, spleen), and organ titers were usually higher than serum titers. Heating to 75° C for 30 minutes had no significant effect on the inhibiting substance in serum. In general, the titers of tissue extracts were reduced by heating to 65° C. It seemed reasonable to conclude that at least part of the inhibition shown by serum and extracts of human tissues was due to a factor other than specific antibody.

(*b*) Comparable results were found with normal rabbit and guinea-pig tissues

(*c*) Preparations of perfused organs were still inhibitory, but were usually reduced in activity two- to fourfold, suggesting that hemaglobin as well as tissue cells contained the inhibitory substance.

(*d*) Extracts of human, chicken, sheep, and rabbit red cells were prepared by mechanical disruption. The supernatants were tested for capacity to inhibit agglutination of chick cells by influenza (and mumps) virus. The findings clearly indicated a correlation between the capacity of the red cells to agglutinate with these viruses, and the inhibition titers produced by extracts of red cells. Thus, human ar ... extracts of these c ... poorly with the ... varied

(*e*) Extracts of human and chick cells did not neutralize the infectivity of influenza viruses, and did not fix complement.

(*f*) The substance in human cells responsible for inhibition was distinct from the A and B substances and the Rh factor

(*g*) The inhibitory agent in human and chicken cells was destroyed by heating at 65° C. for 30 minutes

(*h*) Chicken red cells were treated with influenza virus at 37° C. till they no longer agglutinated, having adsorbed and fully eluted virus Extracts of these cells did not cause detectable inhibition of agglutination It is thus seen that removal of receptors from red cells also removed the factor inhibiting red cell agglutination.

(*i*) The simple explanation of nonspecific inhibition of virus hemagglutination is that the receptor substance released from red cells combines with virus and blocks the union of virus with red cells

There is no simple method available for differentiating nonspecific inhibition from that produced by specific antibody A rise in the serum inhibition titer, however, is undoubtedly due to specific antibody

(*j*) It appears that normal allantoic fluid has an inhibiting effect on virus hemagglutination (Svedmyr, 1946)

THE SIGNIFICANCE AND EXPLANATION OF VIRUS HEMAGGLUTINATION

A number of viruses causes hemagglutination, and these can be grouped as follows (Clark and Nagler, 1943, Burnet, 1945, Burnet *et al*, 1945, Burnet, McCrea, and Stone, 1946)

1 *The mumps-Newcastle disease-influenza group* The members of this group

1944). On the basis of a number of experiments, Miller and Stanley (1944) concluded that 25° C. should be regarded as the standard temperature (see below).

Calculation of Titer

In the presence of virus, chick cells are agglutinated, and fall to the rounded bottom of the special agglutination tube. The red cells form a characteristic sediment at the foot of the tube, and the supernatant column of cell suspension becomes correspondingly clearer as the cells settle down. In Hirst's method, the titer of a virus preparation (or antibody titer of a serum) is read by comparing the density of the lower third of the tube with control standard tubes containing known percentages of cells in suspension, after a fixed period of 75 minutes at room temperature. Thus, if no agglutination occurs in a given tube, the density of its lower third will correspond to a standard representing 100 per cent. of cells in suspen-

of the cells

per cent. or

agglutinated,

that is to say, where 67–50 per cent of cells remain inagglutinated in suspension in the lower third, the reading can be made more accurately with a densitometer (Hirst and Pickels, 1942; Hirst, Rickard, and Whitman, 1942) or spectrophotometer (Schwartz *et al*, 1946). Davies (1947) describes a slide rule method for determining titers.

body titers are plotted on a geometric scale they give a fairly symmetrical probability curve.[1] If the same titers are plotted on an arithmetic scale, the arithmetic mean is not at the peak of the curve, and the value is greatly affected by a few sera of abnormal titer (Hirst et al., 1942) Schwartz et al. (1946) have devised an antibody index based on the arithmetic mean of pooled sera, and suggest that investigations on the population at large may afford a clew to the onset of an epidemic.

CONTROLS

In every test it is necessary to have one tube containing red cells and saline only, to make certain that the cells are not spontaneously agglutinable In CCA-inhibition tests an additional control is needed, to show that the virus preparation is causing agglutination in the absence of serum.

(Commission, 1946 *b*)

THE TECHNIQUE OF CCA AND CCA-INHIBITION TESTS

Hirst's Method

The following method can be thoroughly recommended (Hirst, 1942 *c*, Hirst and Pickels, 1942, Miller and Stanley, 1944)

These tests are performed in small thin "Wassermann" tubes measuring 7 cm by 0.8 cm These tubes must be of high quality and standard specification Each tube in a series must be exactly similar in bore and thickness of wall In tubes showing agglutination, the clumps of cells settle to the foot of the tube forming a "lacy" or granular sediment Correspondingly the supernatant fluid becomes clearer The test is read by assessing the

[1] The geometric mean between two titers a and $b = \sqrt{a \times b} = \frac{1}{2}$ (log a + log b), i.e., the figures are transformed into logs, added and divided by 2

is the optimum amount of red cells in CCA and CCA-inhibition tests. The majority of workers, however, use a 1.5 per cent. or 2 per cent. suspension.

In CCA-inhibition tests, the method should detect a small excess of unneutralized virus, and the lower the concentration of red cells, the smaller the amount of virus required to give a corresponding degree of agglutination, as shown by the pattern of the deposited cells, the concentration recommended by Salk is about the practical limit, as below this point the red cell deposit is too scanty to be read accurately (Burnet *et al.*, 1945).

Antigen

In CCA tests it is desired to estimate the potency of an unknown virus-containing fluid. Serial twofold dilutions are usually made, and an equal quantity of red cells added.

Lauffer and Carnelly [illegible] preparing serial twofold dilutions. [illegible] of virus-containing material is tr[illegible]ng 0.01 M phosphate buffer at pH 7, (i.e., a 1/100 dilution). Solutions containing relative concentrations varying by a twofold factor from 1/200–1/6400 are prepared each by single step dilutions of this 1/100 solution. Then 1 c.c. of a 1.5 per cent. cell suspension is added to 1 c.c. of each dilution, to give final relative concentrations of virus from 1/200–1/12,800. For samples of lesser activity, the first stage dilution is 0.1 c.c. to 2.4 c.c. solvent (1/25). Solutions with relative concentration between 1/50–1/800 are then prepared each by single step dilutions of this 1/25 dilution. By this method, errors are not accumulated as in the case of successive twofold dilutions.

In CCA-inhibition tests it is necessary first to obtain a preparation of virus and titra[illegible] use in such inhibition tests is usually furnished by t[illegible]ifuged allantoic fluid, but purified preparations are [illegible] 1944; Miller and Stanley, 1944). Fluid can be dried, e.g., by the lyophil process and later reconstituted with water (see Dudgeon *et al.*, 1946, Lépine, Sautter, and Reinié, 1946). Infected mouse lung can be used (Twyble and Mason, 1944). When performing a series of tests with unpurified allantoic fluid, the same egg fluid should be used throughout, or discrepancies will arise (see Stuart-Harris, 1943). Lower titers in the inhibition test are obtained using egg-adapted than recently isolated strains of virus as antigen, this variation is not so marked with high titer antisera (Stuart-Harris).

In inhibition tests, each tube contains virus, red cells and antiserum, arranged so that agglutination will occur except in those tubes where it is prevented by the presence of antiserum. Each tube must, therefore, contain at least one agglutinating dose of virus. The practice varies in this respect, and some use 2 or 4 such doses. It is essential for any one worker to be consistent in the number of agglutinating doses used.

Burnet *et al.* (1945) have studied this question. They point out that equilibrium should be reached in so short a time that it becomes immaterial in what order the reagents are mixed. The standard virus concentration should, therefore, be as high as is consistent with obtaining a clear end-point within the range of serum dilutions used. When a single agglutinating dose is used, a true equilibrium may not be reached.

Salk (1944) states that as long as constant proportions of virus and red cells are used, the CCA-inhibition titer of a serum remains constant. For example, if with a 0.125 per cent. cell suspension and 1 agglutinating dose of virus, the titer of the serum is 2560, it will remain the same if 0.25 per cent. red cells and 2 agglutinating doses are used.

Temperature

The agglutinated cells fall to the foot of the tubes more quickly at higher temperatures, but the rate of dissociation of the clumps is also more rapid (Salk,

1944). On the basis of a number of experiments, Miller and Stanley (1944) concluded that 25° C. should be regarded as the standard temperature (see below).

Calculation of Titer

In the presence of virus, chick cells are agglutinated, and fall to the rounded bottom of the special agglutination tube. The red cells form a characteristic sediment at the foot of the tube, and the supernatant column of cell suspension becomes correspondingly clearer as the cells settle down. In Hirst's method, the titer of a virus preparation (or antibody titer of a serum) is read by comparing the density of the lower third of the tube with control standard tubes containing known percentages of cells in suspension, after a fixed period of 75 minutes at room temperature. Thus, *if no agglutination occurs in a given tube, the density of its lower* third will correspond to a standard representing 100 per cent of cells in suspension. On the other hand, if maximum agglutination occurs, the density of the cells *remaining in suspension in the lower third of the tube will be only 25 per cent.* or less. The end-point is that dilution where 33–50 per cent. of cells are agglutinated, that is to say, where 67–50 per cent. of cells remain inagglutinated in suspension in the lower third, the reading can be made more accurately with a densitometer (Hirst and Pickels, 1942; Hirst, Rickard, and Whitman, 1942) or spectrophotometer (Schwartz *et al.*, 1946). Davies (1947) describes a slide rule method for determining titers.

In other methods, the titer is calculated by observing the pattern of the clumped *cells at the foot of the tube after complete settling, this is facilitated by the use of* a mirror under the rack (Lépine, Sautter, and Reinié, 1946).

Titers can be expressed in terms of their common logarithms if desired. If antibody titers are plotted on a geometric scale they give a fairly symmetrical probability curve[1] If the same titers are plotted on an arithmetic scale, the arithmetic mean is not at the peak of the curve, and the value is greatly affected by a few sera of abnormal titer (Hirst *et al*, 1942) Schwartz *et al.* (1946) have devised an antibody index based on the arithmetic mean of pooled sera, and suggest that investigations on the population at large may afford a clew to the onset of an epidemic.

CONTROLS

In every test it is necessary to have one tube containing red cells and saline only, to make certain that the cells are not spontaneously agglutinable. In CCA-inhibition tests an additional control is needed, to show that the virus preparation is causing agglutination in the absence of serum.

albumin sac, the contents of which enter the amniotic cavity at about the 13th day (Commission, 1946 *b*).

THE TECHNIQUE OF CCA AND CCA-INHIBITION TESTS

Hirst's Method

The following method can be thoroughly recommended (Hirst, 1942 *c*; Hirst and Pickels, 1942, Miller and Stanley, 1944)

Correspondingly the supernatant fluid becomes clearer The test is read by assessing the

[1] The geometric mean between two titers a and $b = \sqrt{a \times b} = \frac{1}{2}(\log a + \log b)$, i.e., the figures are transformed into logs., added and divided by 2.

is the optimum amount of red cells in CCA and CCA-inhibition tests. The majority of workers, however, use a 1.5 per cent. or 2 per cent. suspension.

In CCA-inhibition tests, the method should detect a small excess of unneutralized virus, and the lower the concentration of red cells, the smaller the amount of virus required to give a corresponding degree of agglutination, as shown by the pattern of the deposited cells; the concentration recommended by Salk is about the practical limit, as below this point the red cell deposit is too scanty to be read accurately (Burnet *et al.*, 1945).

Antigen

In CCA tests it is desired to estimate the potency of an unknown virus-containing fluid. Serial twofold dilutions are usually made, and an equal quantity of red cells added.

Lauffer and Carnelly (1945), however, recommend the following method of preparing serial twofold dilutions. For samples of high agglutinating activity, 0.1 c.c. of virus-containing material is transferred to 9.9 c.c. of physiological saline containing 0.01 M phosphate buffer at pH 7, (i.e., a 1/100 dilution). Solutions containing relative concentrations varying by a twofold factor from 1/200-1/6400 are prepared each by single step dilutions of this 1/100 solution. Then 1 c.c. of a 1.5 per cent. cell suspension is added to 1 c.c. of each dilution, to give final relative concentrations of virus from 1/200-1/12,800. For samples of lesser activity, the first stage dilution is 0.1 c.c. to 2.4 c.c. solvent (1/25). Solutions with relative concentration between 1/50-1/800 are then prepared each by single step dilutions of this 1/25 dilution. By this method, errors are not accumulated as in the case of successive twofold dilutions.

In CCA-inhibition tests it is necessary first to obtain a preparation of virus and titrate it by a CCA test. Antigen for use in such inhibition tests is usually furnished by the supernatant of lightly centrifuged allantoic fluid, but purified preparations are probably more suitable (Salk, 1944; Miller and Stanley, 1944). Fluid can be dried, e.g., by the lyophil process and later reconstituted with water (see Dudgeon *et al.*, 1946; Lépine, Sautter, and Reinié, 1946). Infected mouse lung can be used (Twyble and Mason, 1944). When performing a series of tests with unpurified allantoic fluid, the same egg fluid should be used throughout, or discrepancies will arise (see Stuart-Harris, 1943). Lower titers in the inhibition test are obtained using egg-adapted than recently isolated strains of virus as antigen, this variation is not so marked with high titer antisera (Stuart-Harris).

In inhibition tests, each tube contains virus, red cells and antiserum, arranged so that agglutination will occur except in those tubes where it is prevented by the presence of antiserum. Each tube must, therefore, contain at least one agglutinating dose of virus. The practice varies in this respect, and some use 2 or 4 such doses. It is essential for any one worker to be consistent in the number of agglutinating doses used.

Burnet *et al.* (1945) have studied this question. They point out that equilibrium should be reached in so short a time that it becomes immaterial in what order the reagents are mixed. The standard virus concentration should, therefore, be as high as is consistent with obtaining a clear end-point within the range of serum dilutions used. When a single agglutinating dose is used, a true equilibrium may not be reached.

Salk (1944) states that as long as constant proportions of virus and red cells are used, the CCA-inhibition titer of a serum remains constant. For example, if with a 0.125 per cent. cell suspension and 1 agglutinating dose of virus, the titer of the serum is 2560, it will remain the same if 0.25 per cent. red cells and 2 agglutinating doses are used.

Temperature

The agglutinated cells fall to the foot of the tubes more quickly at higher temperatures, but the rate of dissociation of the clumps is also more rapid (Salk,

3 Add 1 c.c. diluted antigen to tube 1 and to tube 2 Mix the contents of tube 2 thoroughly, and transfer 1 c c to the third tube Mix and repeat the process, discarding

an be
final

Tube	1	2	3	4	5	6	7
Dilution							
1 in	32	64	128	256	512	1024	2048

5. Incubate at room temperature for 75 minutes in a secluded part of the room. The tubes must not be disturbed at all during this period, and must be absolutely vertical

6. Assess the degree of agglutination in each tube by reference to the set of standards The titer of the antigen is the last tube to show 50 per cent. (++) agglutination This point may fall midway between two tubes

Method of antibody titration.

Before sera can be titrated, it is necessary first to set up an antigen titration as described above

1 All sera should be inactivated at 55° C. for 20–30 minutes

2 Dilute the serum under test ⅛ (0.25 c c. + 1 75) unless the titer is known to be high, when a different dilution may be used When using normal serum, dilute ½.

3 Rack out 8 tubes and 1 control Add saline 0 5 c c to all tubes except no 1 and to the control. Add 0 5 c c diluted serum to tube 1 and to tube 2 Carry 0 5 c c. from tube 2 along the row and discard from tube 8, thus preparing doubling dilutions of serum from ⅛ upwards.

4 Divide the titer obtained in the previous antigen titration by 16, and make up a corresponding dilution in saline. For example, if the antigen titered 1/256 the dilution prepared would be 1/256 divided by 16, equalling 1/16 (0 5 c c + 7 5 c c.).

5 Add 0 5 c c. of this diluted antigen to all tubes and to the control

6 Add 1 c c. of 1 5 per cent. cell suspension to all tubes and control The final dilution of antigen in all tubes is now 4 times that giving ++ agglutination in the original titration, i e , 4 agglutinating units are used.

The final dilutions of serum are as follows

Tube	1	2	3	4	5	6	7	8
Dilution								
1 in	32	64	128	256	512	1024	2048	4096

7 The tubes on the left hand side will probably show no agglutination, but somewhere in the row agglutination will begin. The tube showing 50 per cent (++) agglutination gives the titer of the serum. Frequently the transition is very abrupt, and no tube may actually show ++ agglutination The end-point is then taken as halfway between a tube of density higher than 67 per cent and an adjacent tube of density lower than 50 per cent

8 The control, containing 0 5 c c saline, 0 5 c c antigen and 1 c c cells should show marked agglutination, the density of the lower third being probably 25 per cent or lower

Other Methods

1. Method of Burnet (see Burnet *et al*, 1945).

Burnet uses round-bottomed test tubes of 1 cm internal diameter. Dilutions of serum or virus are made in twofold steps, 5 agglutinating doses of virus are used The final test consists of 0 25 c c virus dilution, 0 25 c c serum or saline, and 0 25 c c of 2 per cent red cells The tubes are shaken and left at room temperature, or sometimes at 4° C, till the red cells have settled The end-point of virus activity, or the serum titer, as the case may be, is read as that degree of partial agglutination arbitrarily regarded as being +. This degree of agglutination is characterized by a central button of inagglutinated cells, surrounded b

Burnet anc

(see below)

giving titers l

suspension The virus was diluted to give one standard agglutinating dose with 2 per cent.

degree of "clearing" of the lower third of the tube as compared with standards. In strongly positive tubes, under 25 per cent. of cells remain in suspension. In weaker tubes 50 per cent or more of cells remain in suspension. In negative tubes there is little clearing of the lower third of the tube and only a small compact disk of cells that have settled to the foot of the tube. These tubes should match the 100 per cent. standard.

Fowl cells.

A fowl (aged 6–18 months) should be bled into citrate-saline. The blood is filtered through muslin and then washed 3 times in saline. Finally the washed cells are "packed" These cells can be used for several days if stored in the refrigerator For rapid spot-testing of allantoic fluid, a 10 per cent. suspension in normal saline is used, but for accurate titrations a 1.5 per cent suspension. For accurate work, a portion of the 1.5 per cent. suspension may be centrifuged in a hematocrit tube to check the actual strength, which can then be corrected if necessary.

Standards and reading results.

In the test proper, one volume of red cell suspension is diluted with one volume of [illegible] 100 per cent of this [illegible] the lower third will [illegible] o per cent. standard [illegible] cent. of cells remain- [illegible]

The standards are prepared as follows

Standard Represents Percentage of Cells in Suspension	*Add Saline, c c*	*Add 1 5 Per Cent Cell Suspension, c c.*
100	1	1
87	1 13	0 87
75	1 25	0 75
67	1 33	0 67
50	1 50	0 50
37	1 63	0 37
25	1.75	0 25

The degree of agglutination is assessed by comparing the lower third of each tube with the above standards. The tubes should be read against an illuminated white ground, and must be handled very carefully so as not to disturb the sediment The standards are, of course, well shaken immediately before use, as any sedimentation would affect their correct strength The results are read as follows

Density of Lower Third of Tube, Percentage of Cells in Suspension	*Degree of Positivity*
Between 100 and 87	−
Between 87 and 75	±
Between 75 and 67	+
Between 67 and 50	++ (the end-point)
Between 50 and 37	+++
Below 37	++++

The end-point is arbitrarily taken as the last dilution in which ++ agglutination occurs No one tube may show ++ agglutination, the point falling between 2 tubes The titer is then taken as halfway between these points.

Method of antigen titration.

Various virus-containing suspensions can be titrated for their CCA potency by preparing falling dilutions, and adding a standard volume of cells Thus amniotic fluid, allantoic fluid, organ suspension, and purified virus preparations can all be tested by the following method, the supernatant being used after light centrifugation

1 Dilute antigen 1/16, if approximate titer is unknown (0 25 c c antigen plus 3 75 c c saline). If the strength is known to be high, this dilution could be increased to 1/32 or 1/64.

2 Rack out 7 tubes for the test, and 1 for the control Add saline 1 c c to all tubes except tube 1, and to the control.

that when the logarithm of activity was plotted against the logarithm of relative concentration, the data fitted a straight line with a slope of unity, as they should if the titration was reliable over a range of concentrations

5. Method of the U.S Army Medical Department.

This method has been recommended so that the results of inhibition tests obtained by various centers may be comparable (*Bulletin*, U.S Army Med Dept., 1946, Whitman, 1947). The total bulk of fluid is 0 75 c c representing equal portions of allantoic fluid (4 agglutinating units), serum dilutions, and 1 per cent human O cells. Recordings are made after 45 and 120 minutes

cells (equivalent to 4–5 doses with 0.5 per cent. cells). The end-point was a standard degree of partial agglutination read after settling of the cells, reshaking, and a final settling, at room temperature throughout.

Guinea-pig cells are said to give results that can be read more easily. It is necessary first to absorb the serum (1/10) with 10 per cent of packed cells, to remove agglutinins for guinea-pig cells, present in most normal human sera (Beveridge and Lind, 1946).

2. Method of American Naval Laboratory No. 1.

For inhibition tests these workers recommend the use of a constant 1/100 dilution of unknown serum, a constant amount of human group O cells, and falling dilutions of known virus (*U.S. Nav. Med. Lab.*, 1943 *b*, Van Gelder, Greenspan, and Dufresne, 1947). The antibody titer is expressed by comparing the amount of virus which causes an arbitrarily selected degree of agglutination in the presence of normal and immune serum.

In CCA tests these workers mix 0.5 c.c. of each twofold dilution of virus with 0.5 c.c. 1 per cent. normal rabbit serum in saline, and then add 0.1 c.c. of 0.75 per cent. of washed human O cells, or chick cells. The serum prevents the formation of a film of cells on the bottom of the tubes, which interferes with the reading of negatives and controls. 0.1 per cent gelatin in saline can be substituted for serum (*U.S. Nav. Med. Lab.* No. 1, 1944 *a*).

3. Salk's (1944) method.

Salk prepares serial twofold dilutions of virus in saline, and adds 0.5 c.c. to tubes as recommended by Hirst. To each tube, 0.5 c.c. of 0.25 per cent. washed chick cells is added. The tubes are well shaken and set aside till the cells are completely settled (½–2 hours). In negative tubes, there is a central sharp disk of cells. In tubes showing maximum (+) agglutination there is a uniform film of clumps of cells covering the entire bottom. Intermediate degrees are scored as ±. The titer of the virus is given as the reciprocal of the highest final dilution giving maximum (+) agglutination.

In CCA-inhibition tests, Salk recommends the use of an antigen partially purified by adsorption and elution. He prepares serum dilutions in 0.25 per cent. red cell suspension, from 1/32–1/1024 in samples from acute cases, and 1/32–1/16,000 in convalescents. To 0.5 c.c. of each serum dilution he adds 0.5 c.c. of virus suspension of twice the highest concentration needed to give maximal agglutination. The test is read by studying the cell deposit at the foot of the tubes. The titer is the reciprocal of the final dilution of serum in which there is complete inhibition of agglutination.

By this method, normal sera usually show a titer below 128, and convalescent sera from 256–2048.

4. Miller and Stanley's (1944) standardized technique.

Miller and Stanley (1944) investigated the variable factors in the CCA test, with a view to introducing a standardized test to serve as an index of chemical purity. They found that the variation in the results of the agglutination tests could be attributed to varying behavior of different batches of red cell, and to temperature. They suggested that 25° C. should be regarded as the standard temperature for performing CCA tests, and furnished a formula to enable the titer at this standard temperature to be derived from the titer at room temperature.

They recommended that in any series of titrations of unknown virus samples a standard purified preparation should be included. They found that purified virus kept at 4° C. remained stable for several months, and gave results in repeated tests which only varied on account of the behavior of the red cells. The average titer of the B9 preparation of virus was 26,000 units per mgm. of protein nitrogen, converted to the standard temperature of 25° C. The standard procedure recommended involves:

Parallel titration of a standardized preparation of virus along with the unknown virus samples.

The CCA activity of the unknowns is then obtained by multiplying the value of their observed titers by the ratio of the theoretical titer of the standard to the observed titer of the standard. The effect of variations due to red cells and temperature are thus cut out.

To obtain the highest degree of accuracy, duplicate titrations should be performed. They found that the chances were 19/20 that differences of 8.4 per cent. between the mean end-points were significant. Lauffer and Carnelly (1945) confirmed this, and found

gen-antibody reaction, using egg virus and immune ferret serum, with the chorio-allantois as the indicator of neutralization (1936 *d*, Burnet, Keogh, and Lush, 1937). He found that there are 2 stages in the interaction between virus and serum. First, equilibrium rapidly becomes established, in the early stages this reaction is reversible. Second, there occurs a slower phase of irreversible inactivation

(*b*) *In the allantoic cavity.* Virus-serum mixtures can be titrated by inoculation in the allantoic cavity. The presence of chick cell agglutination after incubation is taken as denoting failure of neutralization. If 6 embryos are used per dilution, a 50 per cent. end-point can be calculated (Hirst, 1942 *a*, Burnet, 1943 *b*; Bull and Burnet, 1943, Beveridge and Williams, 1944). Examining sera from cases of influenza, Burnet and Beveridge (1943) found that this method recorded a much greater rise in antibody in convalescence than was shown by the CCA-inhibition method.

Burnet and Stone (1946) in work with virus B, used the following technique (see also Beveridge and Burnet, 1946) Mixtures of serum and virus are held in contact for one hour at 4° C. and inoculated in 0 05 c c quantities in the allantoic cavity of 11-day embryos After 3 days incubation at 35° C., a small amount of allantoic fluid from each egg is tested for hemagglutination. With sera containing little antibody, tests are made with mixtures of undiluted serum plus serial tenfold virus dilutions With active sera, virus diluted 1 100 is mixed with equal volume of serum diluted 1-, 3-, 10-, 30-, and 100-fold. Six eggs are used for each mixture, and the 50 per cent end-point is calculated by Reed and Muench's method. The activity of a serum is expressed as the dilution which mixed with 1:100 virus will produce 50 per cent of infections in 3 days. Allowing for the twofold dilutions of virus in all mixtures, the standard virus (B) used in this work had a titer of $10^{6.3}$ With sera which undiluted fail to neutralize virus diluted 1 100, the titer is expressed according to a convention based on the fact that the neutralization curve, when logarithmic concentrations of virus and antibody are used as ordinates and abscissae respectively, is a straight line with a slope of 3 6 1. A serum, therefore, which gives a 50 per cent end-point with virus 1/105, will be ½ the strength of one giving an end-point with the standard 1/100 dilution

When the titer of the virus differed from the value $10^{6.3}$ taken as standard, the serum titers were adjusted according to the formula: $\log S^1 = \log S + \frac{\log T - 6.3}{3.6}$, where S^1 is the corrected serum titer, S the crude serum titer, and T the virus titer. From the work of Knight (1944 *b*, see p 619), it appears that 10 embryos should be used to justify the use of this correction factor.

Virus neutralization by the CCA method.

This technique is fully discussed in Ch LXI. For the sake of completeness, it may here be mentioned that the influenza virus-antibody reaction, as studied by CCA-inhibition, conforms to the general character of such reactions studied *in vivo* or on the chorio-allantois (Burnet *et al*, 1945).

Correlation between neutralizing titers determined by different methods.

There is, of course, at any one examination, no numerical correspondence between the antibody titers found by the CCA-inhibition test, by the mouse infectivity test, and by inoculation in the allantoic cavity. This is not to be construed as meaning that different antibodies are concerned with the 3 reactions. It signifies only that the tissues or cells tested vary widely from one another in their demonstrable susceptibility to influenza virus For instance, Burnet (1943 *a*) tested virus-serum mixtures by the CCA-inhibition test, by allantoic inoculation, and by chorio-allantoic pock counting The CCA-inhibition test showed the greatest evidence of

CHAPTER LXII

IMMUNITY IN INFLUENZA—ACADEMIC AND EXPERIMENTAL ASPECTS

ANTIGEN-ANTIBODY REACTIONS

Virus Neutralization

INFLUENZA antibody neutralizes the infectivity of virus, and this can be demonstrated by different methods *in vivo; in addition*, the CCA-inhibition technique can be employed This has already been fully described (see above).

Virus neutralization tests in animals.

In this type of test, the serum is diluted serially and mixed with a fixed quantity of virus. Alternatively, the serum can be kept constant, and the virus diluted serially. After contact *in vitro* (e g, 1 hour at 37° C and 1 hour at 4° C.), the mixture is inoculated intranasally in mice. Autopsies are performed as animals die, and survivors are killed after 10 days. The lungs are examined for the presence of lesions due to the virus The 50 per cent end-point can be calculated from specific deaths, or from the presence of influenzal lesions in the lungs (see, for example, Horsfall, 1939).[1]

Burnet and Clark (1942) recommend the use of dilutions of immune sera with stock virus obtained from a mouse lung suspension They take as end-point the production of consolidation between ⅙ and ½ of the visible lung surface (thorax opened from the back).

The titration experiments of Horsfall showed that a linear relationship exists between the logarithm of the quantity of virus (PR8) neutralized, and the logarithm of the quantity of animal serum capable of achieving this effect A fivefold dilution of serum was found to result in a tenfold decrease in quantity of virus neutralized. Horsfall and Lennette (1941) found that a linear relationship exists also between the quantity of human serum and the amount of virus A neutralized It is possible, therefore, to determine the maximum amount of virus a given serum can neutralize. This neutralizing capacity is a fixed value, and is independent of the amount of virus used in the neutralization test.

McKee and Hale (1946) have shown that mixtures "apparently neutral" by their failure to produce lesions in mice may not really be neutral, for passage of the lungs may "unmask" active virus They distinguish between "apparently neutral" mixture and "absolutely neutral" mixtures, where no virus is unmasked by serial passage These workers also showed that alternate freezing and thawing did not reduce the protective power of antiserum in mice

Antisera will also neutralize the toxic effects of influenza virus, and this effect is type- and to a lesser extent strain-specific (Henle and Henle, 1946 *a, b*)

Virus neutralization tests in eggs.

(*a*) *On the chorio-allantois* Certain influenza strains produce characteristic pocks on the chorio-allantois, and this property is inhibited by antiserum Mixtures of serum and known virus preparation are inoculated on the chorio-allantois of 12-day embryos After a suitable period of incubation, the eggs are opened, the membranes removed and pocks counted (see, e g., Burnet and Foley, 1940, Burnet and Lush, 1940 *c*) Burnet has carried out important academic studies on the anti-

[1] References are appended at the conclusion of Ch LXIII, p 671 et seq

neutral mixtures, even after prolonged interaction, and irrespective of the amount of antibody present These authors suggest, therefore, that there is no irreversible destruction of virus by antibody The fact that the amount of virus recovered from virus-antiserum mixtures is less than that recovered from virus-normal serum mixtures can be explained in two ways Probably the methods are not perfect, and better technique could detect a greater quantity of virus Or perhaps virus particles are agglutinated by the serum, and carried down on precipitable nonviral tissue.

There seems little doubt, therefore, that antibody does not completely inactivate all the virus particles in "neutral" mixtures The question in dispute is whether a proportion of virus particles is eventually completely inactivated, or whether improved technique would result in all the original infectivity being recovered from such mixtures.

Complement Fixation

It has been known for many years that complement fixation occurs between antiserum and influenza virus; and it was early recognized that the complement fixing and infective powers are partly independent (Smith, 1936, Hoyle and Fairbrother, 1937 *a*, *c*, Lush and Burnet, 1937, Fairbrother and Hoyle, 1937 *a*, Francis *et al*, 1937 *a*, *b*, Tulloch, 1939).

Various materials can be used as antigens in complement fixation tests, for example, tissue (especially lung) extracts, or tissue cultures Of recent years, infected allantoic fluid has been much used (Nigg, Crowley, and Wilson, 1940, 1941; Nigg, Wilson, and Crowley, 1941) These antigens owe their complement fixing properties to 3 components that have been separated by centrifugation (see p. 587) First, the elementary bodies themselves (the 600 S component) can fix complement Second, the soluble substance or 30 S component, remaining in suspension when the EB's have been deposited, also fixes complement. Finally, another component known as < 30S, which remains suspended when 30 S has been thrown down, also fixes complement Of these [illegible]

imp [illegible]

of [illegible]

hancing factor has been found in many human and animal sera Complement should, therefore, be titrated under the conditions of the test. Hoyle (1945) analyzed the CF reaction in influenza by means of the "chessboard" type of experiment, a series of antigen dilutions being tested against a series of serum dilutions The results were plotted graphically, the curve being obtained by drawing a line through all mixtures giving 50 per cent hemolysis. The maximal serum and antigen titers and the optimal antigen titers could thus be estimated When the ratio of maximal to optimal antigen titer was known, it was possible to derive the optimal antigen titer from the maximal titer, and this could be found by a simple titration of antigen with excess serum (see also the studies of Rice, 1947).

In this work, Hoyle confirmed earlier observations that the reaction was complex, and involved the elementary body and the soluble antigen.

The optimal titration technique has also been recommended by Wiener, Henle and Henle (1946), and obviates the zone phenomenon

The pH mobility of soluble substance was found to be definitely smaller than that of serum albumin, and was close to that of alpha globulin, with an iso-electric point close to pH 5 (Bourdillon and Lennette, 1940).

The development of soluble substance has been studied in saline suspensions of ground lungs of mice inoculated intranasally with PR8 (Eaton and Nicewonger, 1940) The antigen appeared in the lung even after one day, although there were no visible lesions The maximal amount of antigen was probably formed during the period of rapid multiplication of the virus, before the appearance of consolidation The antigen disappeared from the lungs after 7–8 days

neutralization, and the allantoic test the least evidence. This implies that the chick red cell is considerably less susceptible to the effect of a given quantity of virus than is the allantoic cavity, which has numerous cells easily invaded by virus.

The effect of antiserum on the infectivity of virus.

It has been described how the neutralizing effect of influenzal antiserum on virus can be demonstrated by a number of techniques. Although the virus in mixtures shown to be neutral by such tests exerts no apparent pathogenic effect, the question arises as to whether or not it is actually destroyed by the antiserum. A number of observations have been made on this point, from which it appears that the action of antiserum on virus is partly reversible in the early stages, but becomes irreversible later, with apparent destruction of at any rate a portion of the virus.

Simple dilution can render infective certain mixtures of serum and virus which are noninfective for mice in more concentrated form; however, only about 10 per cent. of the original infectivity can be restored by such a procedure (Taylor, 1941 *a*; McKee and Hale, 1946). Similar observations have been made by Burnet in eggs (see below).

Papain digestion also reactivates neutral mixtures (McKee and Hale, 1946).

Neutral mixtures do not usually contain enough free antigenic material to stimulate active immunity in mice (Lyons *et al.*, 1944). Further, the treatment of a formolized preparation of virus A with homologous antiserum largely suppresses the capacity of the virus to stimulate the production of antibody or resistance to infection (Beveridge, Stone, and Lind, 1944).

Working with tissue cultures, Magill and Francis (1937) found that chick embryo cells will support the growth of virus when exposed to the action of a potent antiserum, and then washed. Virus is able to survive if it is added to the cells before a relatively weak antiserum. However, if virus and weak serum are mixed before adding to the culture, little growth takes place. With a powerful serum no growth occurs, irrespective of whether the virus or serum is first added to the cells.

The problem has also been studied in eggs. Using strains adapted to amniotic passage, Burnet (1941 *a*) found that immune serum exerted very little neutralizing effect; the embryo might survive for a longer time, but showed the characteristic effects of infection with virus. On the other hand, when strains not specially adapted to amniotic passage were used, neutralization could be demonstrated.

In similar studies, Burnet (1943 *a*) tested the neutralization of virus by allantoic inoculation. The neutralizing power of serum was found to decrease rapidly on dilution, and with suitable mixtures it was easy to demonstrate reactivation by dilution. Even so, there was evidence that some of the virus was rendered inactive. Virus strains well adapted to growth in the allantoic cavity are more difficult to inactivate by serum than strains less adapted to this route.

Mixtures found to be "absolutely neutral" by serial mouse passage could be reactivated by the addition of concentrated heat-inactivated homologous virus, about 10 per cent. of the original virus was reactivated (McKee and Hale, 1946).

Smorodintseff and Shiskina (1946) in an extensive study have compared various methods of recovering virus from neutral mixtures. (1) Dilution was not sensitive enough to "unmask" virus from overneutralized mixtures, although it could be recovered when relatively little antibody was present. (2) Using electrophoresis, virus could be recovered only from mixtures containing a small excess of antibody. (3) Virus could readily be recovered, even from overneutralized mixtures, by adsorption on kaolin or carbon, and inoculation in the form of a suspension in the nares of mice. (4) The most efficient methods of recovering virus were (*a*) filtration through Elford filters (APD 125–175 mμ), grinding the filter pad, and injecting mice, (*b*) centrifugation at 13,000 r.p.m., and washing the deposit prior to animal inoculation.

They showed that a considerable quantity of virus could be recovered from

Forssman Antigen

It should be remembered that Forssman antigen may be present in virus preparations purified by centrifugation of allantoic fluid (Henle *et al*, 1944) Further, rabbit sera prepared by inoculation of virus purified by centrifugation from allantoic fluid may contain Forssman antibody (Knight, 1944 *c*).

ACTIVE IMMUNITY IN EXPERIMENTAL ANIMALS

Active Immunity Induced by Live Virus

Ferrets and mice infected with influenza virus by nasal inoculation prove, on recovery, to be resistant to reinfection for several weeks (see Smith, Andrewes, and Laidlaw, 1933, 1935, Francis and Magill, 1935 *b*, Burnet, 1938, Francis, 1939, Oakley and Warrack, 1940; Eaton and Beck, 1940, Burnet and Clark, 1942, Sugg and Magill, 1946, 1947). When immunity begins to wane, it can be reinforced by vaccination.

Active immunity can be stimulated by the inoculation of live virus by routes other than the intranasal. Mice can be immunized by subcutaneous injection of live virus (Smith, Andrewes, and Laidlaw, 1935, Rickard and Francis, 1938, Andrewes and Smith, 1939). As little as 2 injections of 0·0025 c.c. of neat infected allantoic fluid are sufficient (Burnet, 1941 *c*). Mice can also be immunized by the intraperitoneal route (Burnet, 1938, Rickard and Francis, 1938, Andrewes and Smith, 1939, Francis, 1939, Eaton, 1940 *a*, Eaton and Pearson, 1940, Oakley and Warrack, 1940). Thus, Rickard and Francis injected large doses, and found that mice were immune to nasal inoculation 24–48 hours later. Francis found that a direct relationship existed between the concentration of virus given intraperitoneally and the degree of immunity to nasal inoculation.

Ferrets can also be immunized by subcutaneous or intraperitoneal injections (Smith, Andrewes, and Laidlaw, 1935, Andrewes and Smith, 1939, Francis, 1939). Francis gave subcutaneous injections of live virus, and found that approximately 100 or more intranasal infective doses were needed to give a partial immunity, whereas one infective intranasal dose produced a firm and immediate immunity.

Monkeys have been rendered resistant to a symptomatic infection by the intratracheal inoculation of live virus (Burnet, 1941 *b*).

Less live virus is needed to immunize mice against the homologous strain than against heterologous strains (Smith and Andrewes, 1938, Burnet, 1938). For example, Eaton and Pearson (1940) working with 3 A strains injected intraperi-
[illegible]

strains of PR8, Phila, and a tissue culture strain of swine virus. This dosage gave a solid resistance to infection with the heterologous strains However, when minimal amounts were given, the immunity might be effective only against closely related strains Sugg and Magill (1946) found that ferrets infected intranasally resisted a challenge inoculation of the homologous virus 6 weeks later, but were not resistant to a closely related A strain However, if the animals had been infected twice with the homologous strain they resisted a 3rd inoculation of the related strain. They also showed that ferrets recovered from infection with virus A or B resisted the homologous virus as early as the 8th day of convalescence, but were susceptible to the heterologous strain (1947).

Immunity can also be induced by living virus of lowered virulence. For in-

The peak of complement fixing power of allantoic fluid occurs at 36 hours after inoculation (Henle and Chambers, 1941). Infected allantoic fluid contains both the 30 S component, and the 600 S or elementary body component, but contains much less 30 S than mouse lung extracts (Friedewald, 1943, Friedewald and Pickels, 1944).

Complement fixing activity is completely destroyed at 63° C. and partly at 56° C. (Lennette and Horsfall, 1940). The activity of irradiated allantoic fluids as antigens in the CFT was found to be more stable than their HA capacity, the antigen titer being unaltered after 120 minutes irradiation. Thereafter there was a rapid decrease, probably due to destruction of the 600 S component, but the activity was not completely lost, perhaps due to the survival of the 30 S component (Henle and Henle, 1947).

Flocculation

Flocculation occurs between immune serum and virus (Magill and Francis, 1938 *b*). The peak of flocculating activity develops in infected allantoic fluid after 48 hours (Henle and Chambers, 1941). From the work of Knight (see p. 589) with normal protein, it appears probable that flocculation may often involve normal constituents rather than virus antigens themselves No flocculation was found to take place when collodion particles, or bacterial cells, were mixed with influenza virus and exposed to immune serum (Pearson, 1944 *b*).

Antibody Absorption

Virus neutralizing antibodies can be absorbed (see, e g, Smith and Andrewes, 1938).

Burnet and his colleagues have worked on the absorption of neutralizing antibody by infected mouse lung or egg membrane (Burnet, Keogh, and Lush, 1937, Burnet, 1937 *b*, Burnet and Lush, 1938 *a*). They tested the immune body content of absorbed serum by different techniques. Using the chorio-allantois for the demonstration of antibody, they found that 90 per cent. could be absorbed with egg virus or mouse lung However, sera absorbed with egg virus showed no reduction in antibody when tested by inoculation of mice. Only by absorbing with large quantities of mouse lung was it possible to demonstrate reduction of antibody when tested by both chorio-allantoic and mouse inoculation They concluded that the apparent discrepancy in the result of titration by the 2 methods was due to the nature of the susceptible tissues, and not to any difference in the *in vitro* part of the reaction.

The antibody responsible for CCA-inhibition can also be absorbed from antiserum by treatment with an homologous virus preparation

Complement fixing antibody can also be absorbed, and this technique has been used in the study of the various components of influenza virus

Friedewald (1944 *a*, *b*) has made some studies on adsorption, testing for the presence of antibody by 3 different methods He used purified virus obtained from allantoic fluid as the absorbing agent, and human and ferret antisera After absorption, the sera were centrifuged and filtered through Gradocol membranes to remove virus. All sera were tested by the CCA inhibition and CF techniques, and some by inoculation of mice He found that the infectivity neutralizing, CCA inhibiting, and CF antibodies were completely absorbed by the homologous virus antigen, and that two absorptions were more effective than one The amount of antibody remaining unabsorbed varied inversely with the concentration of virus used to absorb A given concentration of virus absorbs a greater percentage of mouse-infectivity antibodies than either agglutinin inhibiting or complement fixing antibodies.

virus, vaccines derived from heterologous tissues proved less effective than those derived from homologous, as if foreign tissue interfered with the immunizing response. (3) The route of injection, intraperitoneal being more effective than subcutaneous. (4) Heat or formaldehyde decreased the immunizing potency of vaccines, especially those derived from heterologous tissues

Eaton (1940 *a*), working with mice, tested the relative immunizing value of active and inactive preparations Animals were inoculated by the peritoneal route, and tested after 14 days with an intranasal dose of between 1 and 10 MLD. He found that the average minimal immunizing dose of active PR8 virus was about 250 intranasal MLD, and of formolized virus the equivalent of about 8000 MLD.

It is questionable, however, whether purified formolized virus is less potent than material untreated with formalin Stanley (1945 *b*), using purified virus obtained by centrifugation, concluded that at equivalent dosages of virus material the immunizing potency for mice of formolized virus purified by centrifugation, formolized virus purified by adsorption and elution, and infective allantoic fluid were not measurably different.

SERUM ANTIBODIES IN EXPERIMENTAL INFLUENZA

Development after Active Immunization

Serum antibodies detected by various techniques develop in ferrets recovered from influenzal infection (Smith, Andrewes, and Laidlaw, 1933; Francis, 1934–5; 1935), and in ferrets subjected to vaccination with inactivated virus (see Andrewes and Smith, 1939).

Antibodies develop in the sera of mice after the inoculation of live or inactivated virus, and can also be found in the lung, antibodies persist longer in the serum of mice injected with live than dead virus (Oakley and Warrack, 1940). It has been suggested that in infected mice, the main site of production of antibodies is the mediastinal lymph glands (Burnet and Lush, 1938 *b*).

Antibodies have been described in the sera of the following animals after inoculation of live or inactivated virus rabbits (Francis and Magill, 1935 *b*, Fairbrother, 1938), hedgehogs (Stuart-Harris, 1936), pigs (see below); horses (Laidlaw *et al*, 1935; Burnet and Lush, 1938 *a*); guinea-pigs (Bijl and van Genderen, 1939, Burnet and Bull, 1943), monkeys (Burnet, 1941 *b*, Saslaw *et al*, 1946); Syrian hamsters and California kangaroo rats (Eaton and Beck, 1941).

The antibody response in animals is most specific on convalescence from infection, or following only one or two doses of vaccines. If the animals are hyperimmunized by repeated injections, the antibody response is no longer strain specific For the detection of antigenic differences between strains, therefore, convalescent sera, particularly ferret, are preferred (see, e g, Taylor and Dreguss, 1941; Friedewald, 1943)

Various observations have been made on the antibody level when partly immune animals are further exposed to virus Thus, when ferrets, in a state of partial immunity resulting from subcutaneous vaccination, or from the waning of a firm immunity after infection, are given an intranasal inoculation, there is an accelerated production of immune bodies, the titer rises much higher than after a primary infection Fully immune animals, however, show no further development of antibodies after a further injection (Francis, 1939).

Important studies of wide application have been carried out by McLean *et al.* (1945 *b, c, d*) in swine, on the effect of revaccination in immune animals, and on the relationship between antibody response and the dosage of virus inoculated. They used an allantoic fluid vaccine purified by centrifugation and inactivated by UVL or formalin

1 They found evidence of a definite trend towards an increased antibody response (measured by the CCA inhibition test), with an increase in dosage per unit

stance, egg-adapted virus inoculated intranasally in ferrets and mice stimulates resistance in 7–10 days (Burnet, 1937 *a*, 1938, Hyde and Chapman, 1937).

Virus cultivated in tissue culture can also be used to immunize (Magill and Francis, 1936, Rickard and Francis, 1938, Andrewes and Smith, 1939).

Vaccination with adjuvants. It has been found that the addition of certain agents, known as adjuvants, greatly increases the antibody response and the resistance to infection in animals injected with PR8, killed tubercle bacilli in paraffin oil and "Falba" base have been used (Friedewald, 1944 *a*). *Myco. butyricum* is probably more effective than the tubercle bacillus

Antibodies may be induced against antigenic material in the normal allantoic fluid (Friedewald, 1944 *c*).

Active Immunity Induced by Vaccines

Animals can be immunized effectively with influenza virus inactivated by various chemical and other agents. The immunizing potency of vaccines depends on the content of elementary bodies, and not on the amount of soluble substance present.

Elementary bodies heated at 57° C. were found to immunize mice and ferrets satisfactorily (Fairbrother, 1938, Fairbrother and Martin, 1939). Andrewes and Smith (1939) found that virus inactivated by heat was not as effective as living virus.

Formolized virus, either from mouse or ferret lung or allantoic fluid has been widely used, and stimulates resistance to infection and the development of antibody (Andrewes and Smith, 1939, Eaton, 1940 *a*, Oakley and Warrack, 1940). Formolized virus adsorbed on calcium phosphate is said to be more effective than unadsorbed virus (Salk, 1945). Excessive amounts of formol decrease immunizing potency (Stanley, 1945 *b*). Mice have been immunized with virus precipitated by chemicals such as alum (Bodily, Corey, and Eaton, 1943), and protamine (Chambers and Henle, 1941)

Virus inactivated by ultraviolet light can immunize mice on intraperitoneal injection, but is considerably less effective than live virus (Salk, Lavin, and Francis, 1940, Henle and Henle, 1947). Excessive exposure to UVL causes a loss in immunizing potency (Stanley, 1945 *b*). PR8 showed a gradual loss of immunizing activity on irradiation, although the HA titer was largely unaffected, after the HA test had become negative, the material still induced some immunity. With the Lee strain only prolonged irradiation reduced hemagglutination and antigenicity (Henle and Henle, 1947)

Virus inactivated by soap was found to be a much less effective immunizing agent than live virus (Stock and Francis, 1943)

Drying of formolized virus from the frozen state results in a loss of immunizing potency (Stanley, 1945 *b*)

Vaccines are usually given by the subcutaneous or intraperitoneal route Formolized virus has been given by repeated injections intranasally in mice (Lyons *et al*, 1944).

It may be mentioned here that mice immunized against various respiratory bacteria showed no increased resistance to the intranasal inoculation of virus A (Ungar and Hunwicke, 1941)

Relative Immunizing Effect of Live and Inactivated Virus Vaccines

It is generally agreed that inactivated preparations do not have such a high degree of *antigenic potency as preparations of live virus* (Andrewes and Smith, 1937, 1939, Hare, 1941, Eaton, 1940 *a*, Salk, Lavin, and Francis, 1940, Stock and Francis, 1943, Henle and Henle, 1947, McLean, Beard, and Beard, 1947)

Andrewes and Smith (1939) found that the immunizing efficiency of virus vaccines depended on (1) The titer of the contained virus (2) The source of the

5. Ferrets cannot be so easily protected as mice, and fever and nasal symptoms usually occur, although pulmonary involvement is frequently prevented (Zellat and Henle, 1941).

A curative effect of influenza serum can also be shown in experimental infection

1. If serum is given intranasally in mice up to 6 or even 24 hours after the virus, protection or reduction in the severity of lesions occurs (Henle, Stokes, and Shaw, 1941, Taylor, 1941 *b*).

The serum, or globulin fraction, can be given by spray (Lyons *et al*, 1944).

2. Serum given, even in large doses, subcutaneously or intravenously in mice is not as effective as small doses reaching the lungs after nasal instillation (Smorodintseff and Shiskina, 1940 *a*).

3. Hare (1939) found that the curative effect of serum could operate only if the infecting dose of virus was not much over 1 MLD

THE MECHANISM OF INFLUENZAL IMMUNITY IN THE EXPERIMENTAL ANIMAL

In discussing the question of why animals rendered resistant by vaccination or by recovery from infection are immune, 3 main mechanisms must be considered First the rôle of antibodies, second the importance of the reticulo-endothelial system, and third any changes that may occur in the respiratory tract rendering invasion less easy.

Generally speaking, the presence of serum antibody can be regarded as an indication of a degree of resistance to infection. For instance, Francis and Stuart-Harris (1938 *b*) found that immunized ferrets with serum neutralizing titers over 1/150 were generally resistant. A number of instances has, however, been recorded where animals with high antibody levels have succumbed to infection, and, on the other hand, where animals with low titers have proved resistant. Influenzal antibody can undoubtedly influence the spread of influenza virus *in vivo*, as it has been shown to have a powerful effect in passive immunity experiments It seems doubtful, however, whether influenza antibody, circulating in the blood, can prevent the entrance of virus into the superficially situated epithelial cells of the respiratory tract. This could be effected if antibody is secreted into the mucous secretions of the nose in the experimental animal, as in man (see p. 628), work in the rabbit suggests that this can occur in animals also. The rôle of circulating antibody is probably confined to preventing the spread of virus from the primary focus The experiments of Burnet in monkeys (1941 *b*) give some support to this conception. He found that when monkeys were infected on a number of occasions, by the intratracheal route, although the antibody level was high, a further rise occurred on each occasion. This suggested that the circulating antibody was unable to prevent invasion of the superficial epithelium, and that each antibody rise was due to a slight infection quickly overcome.

An important factor is probably the degree of rapidity with which antibody can be produced in response to infection. Experiments of Sugg and Magill (1946) on infection of actively immunized ferrets illustrate this point. They found that when ferrets with approximately the same antibody titers were inoculated with the same quantity of virus, the more resistant animals were those with the more extensive previous contact with the virus. The ferrets with the more extensive contact evidently more quickly mobilized a higher concentration of antibody. It is probable, therefore, that the protective effect of antibody is partly due to that amount present in the serum at the time of infection, and partly to what can be produced in response to infection

What evidence there is concerning the rôle of the reticulo-endothelial system, does not suggest that it plays any significant part in influenzal immunity. Thus Smorodintseff and Shiskina (1940 *a*) found that virus is not destroyed by the leukocytes of immune animals Virus injected intravenously is destroyed at the

weight. The relationship of the log. of the antibody titer to the log of the dose per 100 lbs. body weight was linear. The dose had, however, a relatively slight effect on the degree of antibody response. For instance, a tenfold increase in the dose of formolized virus gave only a 2 5-fold increase in titer. The increases in titer due to increases in dose were relatively negligible as compared to the degree of the antibody response to the smallest dose of virus.

2. They found the highest titer after vaccination occurred at 7 days, then there was a rapid decline, and the titer after 3 weeks was low. There was some indication that the rate of decline in titer was greater in those receiving the larger doses, and thus having higher titers. When formolized virus adsorbed on alum was used, the peak of the response was slightly delayed (1945 *c*).

3. Revaccination was carried out after 6 weeks, when there was again a definite indication of an increase in titer due to an increase in dose, but the dose had an even smaller influence on the titer attained after the second vaccination than the first.

A much greater rise in titer followed the revaccination than the first inoculation, and the titer declined more slowly.

4. They found that the optimum interval between doses of vaccine for keeping the titer at the highest level was 3 weeks.

Working with rabbits, Gaidamovich and Soloviev (1947) found the antibody content of lymph constantly related to that of blood, and usually representing about 60 per cent. of blood antibody. Only small amounts of antibody could be detected in the regional glands, and none in lymphocytes from thoracic duct lymph

PASSIVE IMMUNITY IN EXPERIMENTAL INFLUENZA

Antisera prepared by immunization of rabbits, ferrets, and horses with repeated doses of virus have definite protective and curative effects in influenzal infections of mice, the sera of ferrets recovered from infection are also effective (Francis and Magill, 1935 *b*, Laidlaw *et al.*, 1935, Hare, 1939, and others, see below) Mouse sera and human convalescent sera have also been used (Henle, Stokes, and Shaw, 1941), also the sera of guinea-pigs or rats injected nasally or intraperitoneally (Hyde, 1942)

The effective antibody is contained in the globulin fraction (see Lyons et al., 1944)

It should be realized in this type of work, that anaphylaxis may follow the repeated administration of serum Thus Hopps and Moulton (1943) found that guinea-pigs could be sensitized to foreign serum, and developed anaphylactic reactions when the "shocking" dose was given by inhalation.

The prophylactic effect of antiserum has been demonstrated in various ways

1. Serum administered nasally in mice protects against a subsequent instillation of live virus—even 100 or more MLD given 48 hours later (Vieuchange, 1940, Henle, Stokes, and Shaw, 1941, Taylor, 1941 *b*; Klein and Stevens, 1945). Serum will also protect against infection following inhalation of atomized virus (Wells and Henle, 1941)

2. The inhalation of immune serum is probably more effective than instillation (Zellat and Henle, 1941), and the degree of protection increases with the time of exposure to the spray (Lyons *et al*, 1944)

3. Serum given by routes other than the nasal, e g, subcutaneously, intravenously, or intra-abdominally is not so effective in preventing pulmonary infection in mice as serum given nasally (Hare, 1939, Smorodintseff and Shiskina, 1940 *a*, Henle, Stokes, and Shaw, 1941, Taylor, 1941 *b*)

4 Instillation of antiserum to one strain of virus A protects mice against infection with other strains of A, but not against infection with B virus (Hare, 1939, Zellat and Henle, 1941).

CHAPTER LXIII

IMMUNITY IN HUMAN INFLUENZA

ALLERGY

CERTAIN observations have been made suggesting that persons may become sensitized to influenza virus, so that on a later exposure they develop allergic manifestations. For example, Bull and Burnet (1943)[1] subjected volunteers to 2 exposures, by spray, of attenuated virus B at intervals of 3 to 6 months. Symptoms occurred as frequently after the second as the first exposure, and were more severe in those with high antibody levels. Virus was found fairly readily in the nasal secretion 48 hours after the first inoculation, but only rarely after the second. It is suggested that the symptoms were allergic in character.

In further work, Beveridge and Burnet (1944) found that unheated or boiled preparations of allantoic fluid infected with virus A or B might induce a skin reaction on intradermal inoculation In children the results of serum tests suggested that a positive skin test resulted from a previous infection with the corresponding virus. A number of children with positive serological tests, however, showed no skin reactivity. Most adults gave well-marked reactions, but the size bore no relation to the titer of serum antibodies About 20 per cent. of adults gave skin reactions to an antigen prepared from Newcastle virus, but this was probably due to a widening of the specificity of reactivity brought about by previous exposure to influenza virus

Henle *et al* (1946 *a*) in experiments on infection by inhalation found that there was some evidence that previous exposure to the virus resulted in a short incubation period, and that this was an allergic manifestation

ACTIVE IMMUNITY FOLLOWING NATURAL INFECTION

The resistance to reinfection following an attack of influenza is notoriously short. It must be realized, however, that in a proportion of cases where a second attack has followed a first after a short interval, the infecting agents may have been of different antigenic composition. Thus, the second infection may be due to a different strain of the same type (Magill, 1941), or to the other type of virus (see p 580)

ACTIVE IMMUNITY FOLLOWING EXPERIMENTAL INFECTION

It has been suggested that human beings can be actively immunized by the application of living virus to the nasal mucosa (Smorodintseff *et al*, 1937) Burnet and others have administered preparations of egg virus (A and B) of attenuated virulence for man by the nasal route; these preparations can be administered conveniently by spray (Burnet and Lush, 1938 *a*, Bull and Burnet, 1943; Mawson and Swan, 1943).

This type of immunization is now little used, partly because of the relative ease with which killed virus vaccines can be prepared, and partly because of a slight risk entailed by the inoculation of a living agent. Apart from the unknown susce ... e attenuated st ... lets ... 598), and a rise in antibody occurs (see p 667). A second exposure some months later usually gives rise to a less severe attack (Francis *et al*, 1944 *b*)

[1] References are appended at the end of this chapter.

same rate in organs rich or poor in reticulo-endothelial cells. Splenectomy or blockade does not markedly influence the resistance of normal or immunized mice

A number of observations has been made suggesting that resistance to reinfection *in immune animals is often brought about by* alterations in the physiological function or histological structure of the respiratory tract.

For example, working with mice inoculated intranasally with mouse-adapted strains, Oakley and Warrack (1940) found that the production of lung lesions was essential for the development of resistance to infection, and the production of antibodies. Straub (1939, 1940) concluded that resistance depends largely on the presence of epithelialized metaplastic areas in the bronchial tree; even slight metaplasia gives complete protection Eaton and Beck (1940) came to the same conclusion as Oakley and Warrack, when they used mouse-adapted strains. However, when they used tissue culture or ferret-passed strains, they found that mice became resistant without showing lung lesions. It has been reported that unadapted strains of human origin render animals resistant, and stimulate the production of antibodies without producing lesions in the lungs (Burnet and Clark, 1942).

That immunity can develop in mice without the presence of lung lesions, appears definitely established by the work of Rickard and Francis (1938). When mice were injected intraperitoneally with large doses of live virus, virus could be isolated from the lungs, being present in highest amount 48–72 hours later. These mice showed lung lesions, and were resistant to nasal inoculation. However, when mice were injected subcutaneously with live virus, or intraperitoneally with tissue culture virus, immunity was still produced, but no virus was found in the lungs

Important observations have been made in ferrets, which show that the production of the immune state after nasal instillation of virus is a complex process dependent on several factors (Francis and Stuart-Harris, 1938 *a*, *b*, Stuart-Harris and Francis, 1938). These authors found that ferrets, on recovery from infection, were resistant to nasal instillation of zinc sulfate, and to iontophoresis, for a short period This resistance appeared to be due to the altered histological structure of the nasal mucosa (see p. 600). It seemed, therefore, as if histological changes could account for the resistance to reinfection present in animals recently recovered from infection. When they investigated the effect of repeated nasal instillations of virus, they found the animals to be fully immune although the microscopic appearances of the mucosa were normal. In this case they attributed the immunity to the very rapid repair of the nasal mucosa, and to the development of antibodies.

There seems little doubt that both in ferrets and mice inoculated nasally both antibodies and histological changes are of importance in the acquisition of the immune state.

and the supernatant removed To elute virus, saline equal in volume to 1/10 that of the harvest material, was added to the cells The containers were incubated in a 37° C. water bath for 2½ hours. After low-speed centrifugation, the supernatant (containing the virus) was removed from the packed cells Formalin and merthiolate to give final concentrations of 1/2,000 and 1/20,000 respectively were added After 4 days, sterility tests were performed, and the bottles proving sterile pooled into lots containing equal quantities of PR8 and Lee viruses The efficiency of recovery of virus in the large scale process was over 70 per cent., and comparec [illegible] small scale

Hare and Mackenzie (1947) [illegible] red cell titration and antigenicity te [illegible] with falling dilutions and estimate tl [illegible] also Eddy, below).

Formolized vaccine obtained from allantoic fluids by adsorption to, and elution from, chick red cells was used in the extensive studies of the Commission on Influenza of the U.S Army (see below).

Beveridge and Burnet (1946) describe their technique for dealing with large numbers of eggs

McClelland (1946) has shown that typhus and influenza vaccines can be prepared from eggs infected in the yolk sac with the former agent, and in the allantoic cavity a few days later with influenza virus

5 *Centrifugation*, which has proved so effective in obtaining purified preparations of virus for laboratory experiments, can also be used for large scale production (Stanley, 1945 *b*, 1946, Taylor *et al*, 1945, Henle *et al*, 1946 *b*) For this purpose, the Sharples centrifuge is most suitable, Taylor *et al* (1945) recommend that the eggs be harvested in a chamber with UVL irradiation, and that the fluid be aspirated directly into a small harvesting flask. They used a modified type of centrifuge in which fluid is retained in the bowl during deceleration, to allow dispersion of virus aggregates by shaking, before withdrawal of the final concentrate, to "run through" 40 liters takes 20 hours, and gives an 800-fold concentration by volume The final product is a suspension of practically pure virus. They found that the yield of virus is about 90 per cent. or more of that initially present in the allantoic fluid

Stanley (1945 *b*) prepared vaccines containing 1-10 mgm. of virus per c c He found that vaccines treated with minimal amounts of formaldehyde or by exposure for a short time to UVL retained their full CCA activity and immunizing potency for mice Storage at 4° C. (but not higher temperature) resulted in maintenance of activity for at least 2 months To minimize the risk of bacterial contamination, he recommended the addition of 1/10,000 formalin and 1/100,000 phenylmercuric nitrate immediately after harvesting It was possible to prepare a vaccine by centrifugation containing 5 mgm Lee (B) and 2 5 mgm. each of Weiss and PR8 (A) viruses

Strains Included in Vaccines

In the earlier work it was usual to prepare the vaccine from one strain of virus only, and the WS strain was frequently used Owing to the discovery of antigenic variations between strains, and of the clear-cut differences between types A and B, it is now customary to use virus B and perhaps 2 strains of A. The strains chosen must not be highly specific, but should contain as wide a range as possible of the known antigenic components of the type. PR8 is probably the most popular A strain, and Lee of the B strains The Weiss strain of A has also been used to a considerable extent It is probable that a more recently isolated B strain should be used as well as the Lee (see Burner and Stone, 1946).

Assay of Vaccines

Various methods of assay have been used, usually depending on challenging mice, immunized with the vaccine under test, by the nasal route. These tests have not always proved satisfactory and it is now common practice in North America to rely more on the production of virus neutralizing antibodies in mice. For example, Eddy (1947) reported the following experiments carried out in attempting to formulate such a test

ACTIVE IMMUNITY FOLLOWING VACCINATION

Source of Vaccine

Older type of vaccine.

In earlier experiments, difficulty was encountered in obtaining a sufficient bulk of virus, free from foreign material. The types of vaccine that were used included

1. Formolized mouse lung, which produced a very satisfactory state of immunity in mice (Andrewes and Smith, 1937, Stuart-Harris, Smith, and Andrewes, 1940; Taylor and Dreguss, 1940 *b*).
2. Virus grown in tissue culture (Francis and Magill, 1935-6, 1937 *a*, Francis, 1937, Stokes *et al.*, 1937 *b*, Martin and Eaton, 1941; Siegel and Muckenfuss, 1941, Eaton and Martin, 1942, Siegel *et al*, 1942 *a*).
3. Virus grown on the chorio-allantois (Burnet and Lush, 1938 *a*).
4. Elementary bodies prepared by differential centrifugation of infected tissue, heated at 57° C. (Fairbrother, 1938).

The complex vaccine of Horsfall and Lennette.

These workers (1940 *a*) found that some ferrets experimentally infected with influenza developed distemper in convalescence A vaccine was prepared from their lungs and spleen, and given to stock ferrets. Subsequent tests showed that these animals were immune to distemper and influenza The influenzal antibodies persisted for a longer time than usual, and a marked rise was produced in human subjects also. The vaccine was difficult to prepare, and the beneficial effects could not readily be reproduced.

The vaccine was used in a group of 3500 persons, and appeared to give good protection against influenza A that broke out 4 months later, see Table 28 (Horsfall *et al*, 1941). The most effective vaccine in stimulating a rise in antibodies was one prepared from chick embryos infected with virus A, and the X strain of canine distemper (Horsfall, Lennette, and Rickard, 1941).

Results suggesting the protective value of this vaccine have been reported by others (Brown *et al*, 1941, Dalldorf, Whitney, and Rushin, 1941, Martin and Eaton, 1941, Eaton and Martin, 1942)

On the other hand, unsatisfactory results, as regards protection or antibody response, have been reported (Martin and Eaton, 1941, Hare, Auger, and McClelland, 1942, Hirst *et al*, 1942, Siegel *et al*, 1942 *b*)

Large scale production of vaccine from allantoic fluid.

Practically all vaccines are now prepared from allantoic fluid by various procedures, and this will be discussed in some detail, with particular reference to large-scale production

The main advantages of allantoic fluid vaccines are (*a*) The high degree of purification *and concentration of virus that is possible* (*b*) *The absence of risk of serious* contamination in preparation (*c*) As compared with the use of animals the egg is cheap (*d*) Concentrated preparations remain stable in the refrigerator for about a year (Salk *et al*, 1945 *b*). Allantoic fluid treated by various methods yields virus in sufficient quantity and concentration for the manufacture of vaccines

1. Alum-precipitated inactivated vaccine (Bodily, Corey, and Eaton, 1943)
2. Virus concentrated by *the freezing and thawing process* can also be used (Hirst, Rickard, and Whitman, 1942, Hirst, Rickard, and Friedewald, 1944) (see Table 28).
3. Henle *et al* (1946 *b*) have used a number of vaccines (*a*) Formolized and dialyzed fluids containing one or more strains (*b*) Allantoic fluid precipitated with protamine. (*c*) Formolized and dialyzed allantoic fluid dried by lyophilization They found that this process *caused some loss of immunizing capacity for mice*
4. Vaccine can be prepared by the *red-cell adsorption and elution process*, yielding a fluid concentrated about tenfold (Francis and Salk, 1942, Hare *et al*, 1943, Hare, Stamatis, and Jackson, 1943, Beveridge and Burnet, 1946, and see Table 28) Hare, Curl, and McClelland (1946) have reported on the value of this method for obtaining large quantities of virus A and B They inoculated 12-day eggs in the allantoic cavity with PR8 or Lee virus The eggs infected with PR8 were incubated for 48 hours at 37° C, 35° C being used for the Lee strain (It has since been found that 35° C. is optimal for both strains) In the process of harvesting, the chorio-allantoic vessels were intentionally torn, to allow bleeding into the cavity The harvested material was kept in the refrigerator overnight,

can be advanced to account for the failure to protect a number of persons in these experiments In certain cases the strain of virus included in the vaccine was found subse

this

gan,

cases of so-called "Y" infection In other cases, the vaccine was given either too shortly or too long before the outbreak.

Doubtful Results

Other workers obtained results that could be considered as encouraging, yet without, for various reasons, affording clear-cut proof of the value of the vaccines used (Stokes *et al*, 1937 *b*, Salk *et al*, 1945 *b*, Friedman, 1946).

In a number of

the absence of an e

Med. Lab, 1943 *c*,

Results of Vaccination against Experimental Exposure

Experiments have also been performed where immunized persons have been subsequently exposed to infection by atomized homologous virus Henle, Henle, and Stokes (1943) obtained satisfactory evidence of protection against virus A by this means, even 4 months after vaccination (see also Stokes and Henle, 1942).

Francis *et al* (1944 *a*, 1945) found protection against virus A after 2 weeks, but this had largely passed off after 4½ months.

A vaccine of virus B was also found to give satisfactory resistance to the homologous agent administered by spray (Salk *et al*, 1945 *a*).

Satisfactory Results

There has been a number of large scale vaccination campaigns where the reported results can be considered definitely encouraging, and statistically significant (see Table 28 for full details) The largest campaign so far reported is that of the Commission on Influenza of the U S Army.

Campaign of the Commission on Influenza.

The Commission on Influenza, U S Army, carried through a large scale experiment on the prophylactic immunization of several thousand troops The results were reported in a preliminary

later (Francis, 1945, Rickard,

1945 *a*, Eaton and Meiklejohn,

Menke, and Francis, 1945; Magill *et al*, 1945)

The vaccine was obtained from allantoic fluid by adsorption to, and elution from, chick red cells It contained strains PR8 and Weiss (A) and Lee (B), and was formolized Phenylmercuric nitrate was added as a bacteriostatic.

The vaccine was used in a single dose of 1 c c given subcutaneously. Controls received saline antiseptic solution only The vaccinations were begun in 6 different centers between October and early December 1943 A severe outbreak of influenza occurred in November.

The reports from the 6 centers, briefly, were as follows

1 At the University of Minnesota, the epidemic began 11 days after vaccination and the attack rate was 2 7 per cent. in the vaccinated group as compared to 9.06 per cent. in the controls The epidemic was proved to be due to virus A by isolation and serological response in a high proportion of the cases (Rickard, Thigpen, and Crowley, 1945).

2 In Iowa, Hale and McKee (1945 *a*) began their vaccination campaign at the beginning of the epidemic, and even so found a decreased incidence of the disease in the vaccinated group

1. Groups of mice received an intraperitoneal injection of test vaccine, neat, and *in varying dilutions. Two weeks later, a proportion of the mice was bled* from the heart, and the blood was pooled. Virus neutralization tests with this serum were carried out in mice by the nasal route. At the same time, the remaining immunized mice were challenged with an amount of virus equivalent to that used in the virus neutralization tests.

2. For the PR8 and Weiss (A) strains it required 63–125 times more vaccine to induce resistance, than to produce antibodies capable of neutralizing the same *amount of virus. For the Lee strain, approximately 5 times as much vaccine was* needed.

3. In some tests with virus vaccines, the end-point was taken as the greatest dilution of vaccine which produced immune serum capable of protecting 50–100 per cent. of mice against the challenge dose of virus A control vaccine showed an end-point for all 3 viruses of 1/125 or 1/625.

Dosage and Route of Inoculation

For the sake of convenience in mass inoculation campaigns, it is usual to give only one dose of vaccine. With modern purified vaccines a dose of 1 c c may contain up to 10 mgm. of virus (McLean *et al*, 1945 *d*, Stanley, 1945 *b*), in practice, however, very much smaller doses are used, owing to undesirable reactions with large amounts.

Although only one dose is usually given, it should be realized that as practically all adults have already been infected with influenza, this acts like a second or so-called "booster" dose. There is no doubt, that to keep the level of circulating antibody as high as possible, more than one dose should be given, particularly through the winter months.

Vaccines are usually given subcutaneously, but the intradermal and intramuscular routes have been used.

Complications of Vaccination

Certain workers have found quite a high incidence of local or systemic reactions after inoculation of vaccines Florman, Poindexter, and Council (1946) were unable to relate these reactions to initial antibody level, or to subsequent production of antibodies Reactions of this type are probably largely related to the virus content (Francis, 1947 *b*, *d*)

Ratner and Utrecht (1946), from a review of the literature and a study of a group of allergic children, conclude that serious and even fatal allergic manifestations may ensue in persons sensitive to egg white All hazard can be eliminated by the intracutaneous inoculation of 0 02 c c of undiluted vaccine before any prophylactic dose Those giving a moderate reaction should be given adrenalin along with the vaccine. Those giving a more severe reaction should receive the vaccine in divided doses Those giving a very severe response should not receive vaccine at all.

Bacterial Vaccines

It is not generally believed that bacterial vaccines have any effect in lessening the incidence of true virus influenza, although they may protect to some extent against upper respiratory disease (see, e g, Brady, 1942)

THE RESULTS OF VACCINATION IN THE PREVENTION OF INFLUENZA

Unsatisfactory Results

A number of workers has obtained definitely unsatisfactory results (see, e g, Andrewes, 1937, Stuart-Harris *et al*, 1938, Stuart-Harris, Smith, and Andrewes, 1940, Siegel *et al*., 1942 *a*, Hare, Stamatis, and Jackson, 1943) Various explanations

3. In California, Eaton and Meiklejohn (1945) did not find a significant difference in the incidence of the disease in the 2 groups The explanation probably lay in antigenic differences between the infecting virus and that used in the vaccine.

4 In New York, Hirst, Plummer, and Friedewald (1945) found a considerably lower incidence in vaccinated persons, although the epidemic started at the time vaccination was begun.

5. At the University of Michigan, Salk, Menke, and Francis (1945) completed vaccination about a week before the appearance of the first case. The incidence of clinical influenza in the vaccinated was 2 27 per cent. and in the unvaccinated 8 58 per cent. The authors believe that the benefits of vaccination may not be confined to the vaccinated, but confer some benefit on the unvaccinated members of the community also. The strain of virus responsible was closely related to the Weiss strain isolated earlier in 1943

6. In New York and Ithaca, Magill *et al.* (1945) found a significantly lower incidence among the vaccinated.

Experience in Great Britain

Vaccines were widely used in a controlled experiment in 1945–1946, but the subsequent incidence of influenza (B) was too restricted to evaluate the results accurately. Dudgeon *et al* (1946) suggested that there was some lessening of the incidence of infection with B virus. Stuart-Harris (1947) concluded that the vaccine used in these experiments appeared to benefit some large industrial groups, but not smaller communities. He raised the question of whether the benefit of vaccination *en masse* was due more to "herd immunity" than to resistance in the individual.

Conclusions

Certain of the above studies show that under favorable conditions, vaccination shortly before the onset or at the beginning of an epidemic can significantly lower the incidence of the disease, provided the infecting strain is closely related to the strain in the vaccine. The authoritative recent report of the Study Committee on Influenza Vaccination, American Public Health Association, points to the value of vaccination in certain circumstances, but does not recommend its general introduction (Francis, 1947*d*)

SERUM ANTIBODIES IN INFLUENZA INFECTION

In Children

The sera of infants contain antibodies to both swine and human viruses, these are presumably derived from the mother, as they disappear before about 4 months (Shope, 1936*a*, Burnet and Lush, 1938*a*, Rickard and Horsfall, 1941).

It is rare to find antibody in the sera of normal young children (Brown, 1936, Hare and Riehm, 1941) After the age of about 3, the percentage of normal sera containing antibody to human strains increases, but antibodies to swine virus have not been detected under the age of 10–12 (Andrewes, Laidlaw, and Smith, 1935, Shope, 1936*a*, Hare and Riehm, 1941). The antibody response of children to infection is usually highly specific Thus, Burnet and Lush (1938*a*) reported that when children's sera contained antibody, it neutralized only the homologous Melbourne strain Antibody to this strain was found in the sera of children born before the last epidemic, but not in those born later. Whereas absorption with swine virus removed all antibody from the sera of adults, it did not remove antibody to the Melbourne strain from a high titer serum of a child aged 3.

Hare and Riehm (1941) also found that in young children, following primary [illegible] bout 10,

(1945)

TABLE 28

LARGE SCALE CAMPAIGNS AFFORDING EVIDENCE OF THE VALUE OF VACCINATION AGAINST INFLUENZA

Authors	*Subjects*	*Source of Vaccine*	*Strains of Virus Included*	*Controls*	*Subsequent Exposure to Influenza*	*Incidence of Influenza*
Horsfall *et al* (1941)	3455 persons in institutions	"Complex" vaccine of influenza A and distemper viruses		4403 unvaccinated	Influenza A broke out 4 months later	Incidence in controls twice that in vaccinated group
Commission on Influenza (see *Commission*, 1944, Francis and colleagues, 1945, *Amer J Hyg 42*, 1–94)	approx 12,500 Army Forces (male)	Allantoic fluid concentrated by adsorption to and elution from chick r b c, formolized	PR8 and Weiss (A) Lee (B)	Alternate men received saline	Influenza A broke out towards close of immunization campaign	Attack rate 2 22 per cent in 6263 vaccinated men, and 7 11 per cent in 6211 controls
Hirst, Rickard, and Friedewald (1944)	3000 prisoners	Allantoic fluid concentrated by freezing and thawing, formolized	Usually PR8 (A) and Lee (B)	8000 uninoculated persons	Outbreak of "A" occurred one year later	Attack rate in vaccinated considerably lower. Average reduction of incidence 35 per cent
Francis, Salk, and Brace (1946)	600 Army Forces	As for Francis and colleagues (1945)		An unvaccinated group of 1000	Influenza B broke out following month	Incidence of hospital admission for acute respiratory disease 99 1 per 1000 unvaccinated and 11.5 in vaccinated group
Hirst *et al* (1947)	550 Army Forces at Yale University	As for Francis and colleagues (1945)		Unvaccinated group of 1050 cadets separately quartered	Influenza B broke out a few weeks later	Clinical influenza occurred in 12 5 per cent of unvaccinated controls, and 0.5 per cent of vaccinated men
Norwood and Sachs (1947)	366 industrial employees	As for Francis and colleagues (1945)		4280 workers in the same factory	Influenza B broke out almost at once	1 94 per cent of those vaccinated more than 7 days before developed influenza, 8 23 per cent of controls became infected

1941, Burnet *et al*, 1942, Eaton and Martin, 1942, Eaton and Meiklejohn, 1945, Magill *et al*, 1945, Rickard, Thigpen, and Crowley, 1945, Salk, Menke, and Francis, 1945).

For example, Hare, Auger, and McClelland (1942) examined the sera of 32 proven cases of influenza A in Toronto from 1937–1940, using a neutralization test with PR8 in mice. They found that the average initial titer of these patients was lower than the average for the population As far as could be determined, a titer of 1/60 appeared to be the lowest antibody level likely to be associated with resistance to infection In Australia, Burnet and Beveridge (1943) found that 18/19 cases of influenza had very low initial titers

In the Convalescent Phase of Influenza

The sera of convalescents from epidemic influenza usually neutralize the infectivity of human strains of virus in animal inoculation tests (Smith, Andrewes, and Laidlaw, 1933, Francis, 1934–5, Smith and Stuart-Harris, 1936, Francis and Magill, 1936, Smorodintseff *et al*, 1936 *b*, Brightman, 1936, Francis *et al*, 1937 *a*, Stuart-Harris *et al*, 1938, Brown *et al*, 1941, Hare and Riehm, 1941; Taylor and Dreguss, 1941, Sulkin, Smith, and Douglass, 1941, Hare, Auger, and McClelland, 1942).

Convalescent sera also fix complement in the presence of suitable antigens (Smith, 1936, Francis *et al.*, 1937 *b*, Hoyle and Fairbrother, 1937 *a*, Morrison *et al.*, 1939, Tulloch, 1939, Francis, 1940 *d*, Martin, 1940, Brown *et al*, 1941; Eaton, 1941, Eaton and Rickard, 1941, Foley and Burnet, 1941, Pearson *et al*, 1941; Sulkin, Smith, and Douglass, 1941, Hoyle, 1942, 1944, 1946) Antibodies to 600 S and 30 S develop separately in convalescence (Wiener, Henle, and Henle, 1946).

Antibody can also be detected by inoculation of virus-serum mixtures on the chorio-allantois (Burnet and Lush, 1940 *c*, Burnet, Cade, and Lush, 1940), or in the allantoic cavity (Burnet and Beveridge, 1943, Burnet and Stone, 1946).

the

194

Ric

Bev

1946).

When the diagnosis of influenza is attempted by examination of an acute and a convalescent phase sample, every care should be taken that the first (acute) specimen is obtained within 5 days of onset, and the second (convalescent) at least 5 days after the first (see Florman and Crawford, 1944)

During the active phase, the antibody titer is usually low, but rises steeply after about a week to reach its maximum by the 14th day The antibody level rises higher in those with initially low titers than in those with higher initial titers For example, Francis *et al* (1937 *a*) found, by the mouse protection test, that the average *neutralizing titer of sera in the acute phase was 1/26, in convalescence*, the titer rose to 1/210 or even 1/640. The majority of cases in a series due to influenza virus A was found to have neutralizing titers of over 1/60 in convalescence, the average being 1/145 (Hare, Auger, and McClelland, 1942)

The complement fixation test may show a tenfold or greater increase in convalescence, for example, from 1/3.8 in the acute phase to 1/38 in convalescence (Sulkin, Bredeck, and Douglass, 1942), or 1/2 to 1 128 (Hoyle, 1946, see also Nigg *et al*, 1942). Hoyle (1944) regards fixation at a 1/16 dilution of serum as the sigr

it is

it h

by the CCA-inhibition test. They found that the antibody response of children experiencing their first infection with virus A was greatest to the infecting strain and lower to PR8, WS, and swine strains. In late convalescence, the antibodies to swine virus completely disappeared.

The magnitude of the response, measured by the CCA-inhibition test, in infants presumably experiencing their first infection, has been found to be of the same order as that of older children (Adams, Thigpen, and Rickard, 1944).

One may liken the serological response to children to that of ferrets recovered from experimental exposure. The antibody rise is specific, being chiefly to the infecting strain; rises to related strains are slight. With increasing age, the reaction of the child resembles that of the adult

In Healthy Adults

It has been found that the sera of most normal adults, healthy at the time of test, and not recently convalescent from influenza, contain antibody to human strains of influenza virus. This antibody is generally believed to result from previous exposure, resulting in a clinical, or perhaps more frequently, a subclinical infection

Antibody to human strains has been detected by various methods in the sera of normal adults

1. By neutralization tests in animals (Andrewes, Laidlaw, and Smith, 1935, Francis and Magill, 1936, Brown, 1936, Fairbrother and Hoyle, 1937 *a*, Stuart-Harris *et al*, 1938, Tsurumi and Takagi, 1940, Burnet and Clark, 1942).

2. By neutralization tests in eggs (Burnet and Lush, 1938 *a*).

3. By the CF technique (Hoyle and Fairbrother, 1937 *a*, Lush and Burnet, 1937, Fairbrother and Hoyle, 1937 *a*, Tsurumi and Takagi, 1940, Friedewald, 1943).

4. The usual practice now is to titrate antibody by the CCA-inhibition test.

Antibody to swine virus also occurs in the sera of normal adults It is believed that this antibody is due to repeated exposure to human strains, as it were to hyperimmunization, and not to infection with the swine virus (Andrewes, Laidlaw, and Smith, 1935, Shope, 1936 *a*, Fairbrother and Hoyle, 1937 *a*, Burnet and Lush, 1938 *a*, Hare and Riehm, 1941; Kalter, Chapman, and Feeley, 1947). Virus neutralizing antibodies to swine virus have been found in placental globulin (Rake, 1939).

Certain observations suggest that, in nonepidemic times, random samples of serum from the community show a lower titer than is found immediately after epidemic periods (Stuart-Harris *et al.*, 1938, Martin, 1940).

St. Helena islanders. The island of St Helena escaped the great pandemic from 1917 to 1921, although influenza has occurred since that time Clearly, therefore, the study of sera might throw interesting light on the possible rôle of the swine influenza virus in the pandemic Stuart-Harris *et al* (1938) studied the sera of 23 islanders, these persons had never left the island and were alive in 1918 Only one serum had fair neutralizing antibody to the WS strain, and one serum to the swine strain. No influenza had occurred in the island for 6 years at the time of this test, but shortly afterwards, influenza happened to break out Twenty-two of the original sera were reexamined (only a few months after the first test), and many now showed a significant level of antibodies to both WS and swine virus This observation does not suggest that the presence of immune bodies to the swine virus need imply any specific contact with that agent

In the Acute Phase of Influenza

It seems reasonably well established that a low initial titer of antibody is a factor in determining susceptibility to infection Samples of serum removed from persons in the early stages of influenzal infection frequently show somewhat lower titers of antibody against the infecting strain than are usual in a normal section of the community at the time (Hoyle and Fairbrother, 1937 *a*, Stokes *et al*, 1937 *a*, Stuart-Harris *et al*, 1938, Rickard, Lennette, and Horsfall, 1940, Rickard *et al.*,

1941; Burnet *et al*, 1942; Eaton and Martin, 1942, Eaton and Meiklejohn, 1945; Magill *et al*, 1945, Rickard, Thigpen, and Crowley, 1945, Salk, Menke, and Francis, 1945)

For example, Hare, Auger, and McClelland (1942) examined the sera of 32 proven cases of influenza A in Toronto from 1937–1940, using a neutralization test with PR8 in mice. They found that the average initial titer of these patients was lower than the average for the population As far as could be determined, a titer of 1/60 appeared to be the lowest antibody level likely to be associated with resistance to infection In Australia, Burnet and Beveridge (1943) found that 18/19 cases of influenza had very low initial titers

In the Convalescent Phase of Influenza

The sera of convalescents from epidemic influenza usually neutralize the infectivity of human strains of virus in animal inoculation tests (Smith, Andrewes, and Laidlaw, 1933, Francis, 1934–5; Smith and Stuart-Harris, 1936, Francis and Magill, 1936, Smorodintseff *et al*, 1936 *b*, Brightman, 1936, Francis *et al*, 1937 *a*, Stuart-Harris *et al*, 1938, Brown *et al*, 1941; Hare and Riehm, 1941, Taylor and Dreguss, 1941; Sulkin, Smith, and Douglass, 1941; Hare, Auger, and McClelland, 1942)

Convalescent sera also fix complement in the presence of suitable antigens

separately in convalescence (Wiener, Henle, and Henle, 1946).

Antibody can also be detected by inoculation of virus-serum mixtures on the

1946).

When the diagnosis of influenza is attempted by examination of an acute and a convalescent phase sample, every care should be taken that the first (acute) specimen is obtained within 5 days of onset, and the second (convalescent) at least 5 days after the first (see Florman and Crawford, 1944).

During the active phase, the antibody titer is usually low, but rises steeply after about a week to reach its maximum by the 14th day The antibody level rises higher in those with initially low titers than in those with higher initial titers. For example, Francis *et al* (1937 *a*) found, by the mouse protection test, that the average neutralizing titer of sera in the acute phase was 1/26, in convalescence, the titer rose to 1/210 or even 1/640 The majority of cases in a series due to influenza virus A was found to have neutralizing titers of over 1/60 in convalescence, the average being 1 145 (Hare, Auger, and McClelland, 1942).

The complement fixation test may show a tenfold or greater increase in convalescence, for example, from 1/3 8 in the acute phase to 1/38 in convalescence (Sulkin, Bredeck, and Douglass, 1942), or 1/2 to 1/128 (Hoyle, 1946, see also Nigg *et al*, 1942) Hoyle (1944) regards fixation at a 1/16 dilution of serum as the significant level for diagnostic tests (see also Hoyle and Fairbrother, 1947)

inhibition test, is diagnostic (Beveridge and Williams, 1944; *Burnet, Stone, and* Anderson, 1946).

A number of observers has studied the rise and subsequent fall in antibody titer of convalescents over a prolonged period (Francis *et al.*, 1937 *b*; Fairbrother and Martin, 1938; Tulloch, 1939, Horsfall, Hahn, and Rickard, 1940; Eaton and Rickard, 1941, Horsfall and Rickard, 1941). The maximum titer is usually reached between the 10th and 14th day. A decline in titer begins between the 11th and 25th day and continues progressively. The higher the maximum titer, the quicker the decline. By about 2–5 months after an attack, the titer is usually about half that of the maximum. The titer declines slowly, and by about 10–12 months after the attack, is back to its original preinfection level.

Schwartz *et al.* (1946) have shown that examination of pooled sera from the general population after an epidemic shows a high antibody level, and that this falls in a few months

A rise in antibody to swine virus usually accompanies an increase in antibody to human strains (Hare and Riehm, 1941; Horsfall and Rickard, 1941, Bodily and Eaton, 1942; Sigurdsson and Bjarnason, 1946). The titer against swine virus may often be higher than that against human strains (Hare and Riehm).

The antibody response in infected human beings is usually wide, and not strain specific (see Taylor and Dreguss, 1941). For example, the antibody response to infection with virus A was studied in 5 cases of acute influenza by Horsfall and Rickard (1941) using the neutralization test in mice. There was an almost complete lack of strain specificity in the response, and a more or less equal rise and subsequent fall in the antibody against several A strains and the swine virus As the response is not usually strain specific, Magill and Sugg (1944) recommend the use of several strains in neutralization tests. The antibody rise in convalescence is usually type specific. Antibody to B does not, as a rule, rise significantly in A cases, such an occurrence has been described by Bodily and Eaton (1942), who advance the hypothesis that the rise may be in the nature of an anamnestic reaction due to previous infection with virus B A rise in antibody to A virus may occur in B infections (Dudgeon *et al.*, 1946)

In some cases the sera may show a much more marked reaction with the infecting strain that with a stock strain of the same type of A or B virus (Eaton and *Meiklejohn, 1945, Salk, Menke, and Francis, 1945, Dudgeon et al., 1946*). Examining convalescent sera in an epidemic of B infection Burnet and Stone (1946) found that adolescents tended to show a specific response, the rise to the homologous strain being greater than that to stock Lee virus. In adults, on the other hand, the response tended to be nonspecific, in that rise to Lee was greater than that to the current strain These differences were not absolute

Although a rise in antibody, of varying degree, practically always occurs in influenza, it is important to realize that definite cases of the disease *may show no* rise at all (Magill, 1940, Francis *et al*, 1945, Burnet, Stone, and Anderson, 1946, Dudgeon *et al*, 1946)

Antibody neutralizing the toxic effect of influenza virus develops in convalescence (Henle and Henle, 1946 *b*)

In Subclinical Infection

Sampling of numerous sera has shown that a proportion of persons *exposed to* influenzal infection develops a rise in antibody [illegible] techniques, without having had any clinical eviden[illegible] fection has been recorded with virus A (Franci[illegible] *et al.*, 1938, Burnet and Lush, 1940 *c*, Burnet, Cade, and Lush, 1940, Rickard, [illegible] nette, and Horsfall, 1940, Nigg *et al*, 1942, Horsfall, Hahn, and Rickard, 1940, Siegel *et al.*, 1942 *a*, Crowley, Thigpen, and Rickard, 1944, Salk, Menke, and Francis, 1945, Magill *et al*, 1945)

Subclinical infections have also been reported due to virus B (Salk *et al*, 1945 *b*, Burnet, Stone, and Anderson, 1946).

In Experimental Infection

Persons exposed experimentally by nasal instillation or inhalation of virulent or attenuated virus (A or B) develop an increase in antibody, a not inconsiderable proportion of these persons shows no symptoms, evidently suffering from a subclinical attack (Smorodintseff *et al*, 1937, Burnet and Lush, 1938 *a*, Burnet and Foley, 1940, Francis, 1940 *c*, Foley and Burnet, 1941, Bull and Burnet, 1943, Burnet and Bull, 1943, Burnet, 1943 *b*, Mawson and Swan, 1943, *U.S. Nav. Med Lab.* 1944 *b*, Henle *et al*, 1946 *a*, Wiener, Henle, and Henle, 1946).

Most clinical cases of influenza following experimental exposure occur in the group of subjects with the lowest antibody titer, although there are many excep-

vac-

irus,

was

high or low (Salk *et al*, 1945 *a*, Henle *et al.*, 1946 *a*).

The administration of a second dose of live virus (B) 4 months later, was found to give another rise in antibody, although it was not so high as in those sprayed for the first time (Francis *et al*, 1944 *b*).

Correlation of Antibody Titers Determined by Various Methods

It is generally agreed that there is a close qualitative correlation between the results obtained by the various methods for the detection of antibody. That is to say that if antibody is found by one method it will usually be found by others as well, if antibody shows a significant rise in convalescence when tested by one method, it will show a rise similar in magnitude when tested by another method Some of the observations that have been made comparing various tests are as follows

The development of virus neutralizing, CF and flocculating antibodies in acute and convalescent sera was found to show good agreement (Henle and Chambers, 1941)

In general, there is good agreement between the results of virus neutralization tests conducted by the CCA-inhibition technique and by intranasal inoculation in mice (McClelland and Hare, 1941; Bodily and Eaton, 1942, Henle, Henle, and Stokes, 1943, Burnet *et al*, 1945)

Hirst (1942 *c*) investigated this problem, using a number of human and ferret

ization and complement fixation with 600 S; there may be a different antibody for fixation with 30 S (Wiener, Henle, and Henle, 1946).

The Significance of Antibody to the Swine Virus in Human Sera

There is a wide distribution of immune bodies to the swine influenza virus in adult human sera, and there are 2 alternative theories advanced to explain their presence.

1. It has been suggested that the virus of swine influenza *represents the human* strain that caused the 1918 pandemic (Laidlaw, 1935; Andrewes, Laidlaw, and Smith, 1935, Shope, 1936 *a*). That is to say, that the human pandemic strain does not now attack man, but only pigs, and the present human virus is a variant of the original. The evidence upon which this theory was based is as follows:

(*a*) There has been no later pandemic of human influenza in any way comparable to that of 1918. At the present day there does not appear to be any influenza virus, attacking man, of such virulence as was manifested in 1918.

(*b*) Swine influenza broke out at the time of the pandemic, and many persons thought that they were one and the same condition. Swine influenza has not died out, and the virus is still being propagated under natural conditions

(*c*) The properties of the swine and human influenza viruses, as isolated today, are virtually identical. They can, however, be differentiated antigenically.

(*d*) The distribution of antibodies to human and swine influenza viruses in the human serum at different ages may be important in this connection. Thus the majority of adults, and a slightly lower number of children's sera neutralized the WS strain (Andrewes, Laidlaw, and Smith, 1935). Antibodies which neutralized the swine virus were regularly present in the sera of adults, but were absent from the sera of children under 10. Further, Shope (1936 *a*) in the United States found *swine influenza antibodies to be absent from sera of children below 12.*

It appeared from these observations that adults had been exposed to the swine influenza virus presumably during or prior to the 1918 pandemic, and had developed immune bodies. Children, however, born since the pandemic, had not been so exposed and had only developed immune bodies to the prevalent human type of virus The main basis for this theory was the demonstration of immune bodies in the sera of adults, while absent from children's.

2. The alternative view, that the presence of antibody to swine virus can be explained with reference to the human strain alone, was expressed by Burnet and Lush (1938 *a*) The following facts can be adduced in support of their contention which is now accepted as being almost certainly correct

(*a*) The swine and human influenza viruses share a common antigen (see p 587).

(*b*) *Hyperimmunization with the human virus in animals results also* in the production of antibodies to the swine virus (Francis and Shope, 1936, see p. 594).

(*c*) Horse antiserum prepared by injection of WS virus acts on swine virus as well (Burnet and Lush, 1938 *a*)

(*d*) During convalescence from influenza contracted from a ferret infected with human virus, Stuart-Harris developed immune bodies to both strains of virus (Smith and Stuart-Harris, 1936).

(*e*) Convalescents from influenza on St Helena, who had never been exposed to the 1918 pandemic, developed antibodies to both strains (Stuart-Harris *et al*, 1938).

(*f*) The serum of children is poor in antibody, but what there is proves highly specific and cannot be absorbed by swine virus (Burnet and Lush, 1938 *a*) These children have probably had only slight contact with human virus and no hyperimmunization *has resulted, hence the specificity*

(*g*) Adult serum contains antibody acting on both human and swine viruses Although of high titer following recovery from infection, the level soon falls In the majority of adult persons the influenzal antibodies appear to be not highly specific, and can be absorbed with swine virus

Antibody to swine influenza in human sera does not appear to indicate contact with that particular virus, but is a group antibody produced by repeated contact and hyperimmunization with the human virus, which possesses a common antigen

PASSIVE IMMUNITY IN HUMAN INFLUENZA

It has been claimed that single or repeated inhalations of 2–3 c.c. of atomized antiserum reduces the incidence of influenzal infection (Smorodintseff, Gulamow, and Tschalkina, 1940).

Stuart-Harris *et al.* (1938) injected large doses of serum prepared in the horse, but were unable to say that the results obtained were specific.

SERUM ANTIBODIES FOLLOWING VACCINATION

Significant rises in antibody after vaccination were found by the earlier workers, and the antibodies were shown to persist for at least 5 months (Francis, 1937, Francis and Magill, 1937 *a*).

This question has been extensively studied of recent years, and the following are the more important observations

1. There is general agreement that the same information as to the presence of antibody and the extent of its rise subsequent to vaccination can be obtained by any of the usual tests. The CCA-inhibition test, however, is now most used (see [illegible]

2. There is a wide individual variation in the response of human beings to the same preparation (Hirst *et al*, 1942). While the majority will show a fourfold or greater rise to one of the components of the vaccine, it is unusual for antibodies to develop to all components equally (see Florman, Poindexter, and Council, 1946).

3. The best antibody response occurs in those with an initial low titer, those with a high titer showing only slight rises (Eaton and Martin, 1942, Magill *et al.*, 1945; Rickard, Thigpen, and Crowley, 1945, Salk, Menke, and Francis, 1945).

4. The maximum rise in antibody occurs in 10–14 days, and then begins to decline One can expect antibody increases of 6–9 fold 2 weeks after inoculation. Even after 2–3 months there is a considerable drop Persons developing the highest titers tend to show the most rapid decline After 6–9 months the titer may be from ¼ to ½ of the maximum, and remains above the initial level for about a year (Eaton and Martin, 1942, Hirst *et al*, 1942; Henle and Henle, 1945 *a*, Magill *et al*, 1945, Salk, Menke, and Francis, 1945, Salk *et al.*, 1945 *b*) For example, using a concentrated vaccine (freeze-thaw process) the mean antibody rise detected by CF and CCA-inhibition was 6-fold at 2 weeks, and 3-fold about a year later (Hirst, Rickard, and Friedewald, 1944).

There may be a marked negative phase a few days after injection (Hare *et al*, 1947).

5. Antibody rises produced by potent vaccines given subcutaneously are as marked as follow natural infection (Hirst *et al*, 1942, Hare *et al*, 1943; Rickard, Thigpen, and Crowley, 1945)

Although it is unwise to be too definite, if a titer of over 1/128 in the CCA-inhibition test develops after vaccination there is a considerable likelihood of protection (see Henle *et al*, 1946 *b*)

6 The actual physical amount of virus injected in the vaccine is the main factor that determines the height of the antibody response, apart from variations in the person injected, the mean geometric antibody response increases parallel with the amount of virus injected (Hirst *et al.*, 1942, Henle *et al.*, 1946 *b*). The degree of antibody response in man produced by a vaccine is highly correlated with immunizing capacity for mice (Henle *et al.*, 1946 *b*)

Better responses are obtained, therefore, when concentrated vaccines are compared with diluted preparations or with simple allantoic fluid (Hirst, Rickard, and Whitman, 1942, Hare *et al*, 1943, 1947, Hirst, Rickard, and Friedewald, 1944).

It appears that much the same effect can be produced by giving a larger dose (e.g., 3 c.c.) of simple allantoic fluid (Henle *et al.*, 1946 *b*).

7. The effect of inactivation of virus on antibody response has been studied. Thus Hirst *et al.* (1942), using allantoic fluid, found that similar titers were obtained after inoculation of active virus, formolized virus, heated virus, or dried inactivated virus

They found that a vaccine composed of ground infected embryos diluted with infected allantoic fluid gave a greater response than allantoic fluid only, but the antigenicity of such a preparation was decreased by formolization.

8. The antibody response of vaccinated persons is not strictly strain specific, resembling in this respect the response of infected adults. There is some suggestion that the response after vaccination may be more specific than that following infection (see Bodily and Eaton, 1942).

9. As regards the effect of revaccination, those who develop a significant rise in antibody mostly fail to develop a further rise after a repeat injection given within a few weeks (Beveridge, 1944 *b*, Salk *et al*, 1945 *a*). This may be explained by suppression of the antigenic properties of the second injection by circulating antibody (Beveridge, Stone, and Lind, 1944).

There does not seem to be any advantage in giving more than 2 injections within a short interval, as the geometric mean antibody levels are not increased thereby (Hare *et al.*, 1943; Henle *et al*, 1946 *b*).

Revaccination after a lapse of some weeks will cause a further rise in antibody level. By repeated injections every 6–8 weeks, it should be possible to maintain a high level of antibody throughout the winter months. (See the observations of McLean *et al.*, 1945 *d*, on revaccination of swine)

10 It has been reported that vaccinated persons who become infected during the period when their antibody is falling, show a secondary rise, if infected in the early stages, while the antibody titer is increasing, the rise is prolonged (Siegel *et al.*, 1942 *a*).

11 Occasionally, inoculation of potent vaccines may fail to stimulate a demonstrable rise in antibodies (Stokes *et al*, 1937 *a*). Later observations have shown that this usually occurs only in those with high initial titers. Some persons who fail to develop antibody to the strains included in the vaccine may do so to related viruses (Florman, Poindexter, and Council, 1946).

12 It has been shown that the rise in antibody titer after 1 intradermal injection is considerably higher than after 2 such injections, or 1 subcutaneous injection (Van Gelder, Greenspan, and Defresne, 1947).

Serum antibodies after use of "adjuvants."

Henle and Henle (1945 *a*) compared the antibody responses in subjects vaccinated with virus A and B in saline, and the same agents emulsified in "Falba" and mineral oil In the persons vaccinated with adjuvants, the antibody titers rose more slowly than usual to reach a peak after 3 months, when they were about 5 times as high as those in the virus-saline group Even after 12 months, the levels in the adjuvant group were still above the maxima reached by the controls, and the majority of persons was probably protected (Henle *et al.*, 1946 *b*).

MECHANISM OF INFLUENZAL IMMUNITY IN HUMAN BEINGS

It is still imperfectly understood what mechanisms underlie resistance to influenza, but the work of the last 10–15 years has clarified many aspects of the problem (see in particular, Francis, 1941–2) Obviously both the parasite and the host are concerned

As regards the influenza virus, there are 2 distinct antigenic types, A and B, which give rise to no cross immunity An attack of influenza A will not immunize against influenza B. Second attacks of influenza at a short interval may well, there-

fore, be due to infection with a different type, and this has actually been described (see p 580). Antigenic variations within the type may be considerable, and it is not impossible that a second attack may be due to another strain of the same type. Then there is the question of so-called influenza Y (see p. 580), which may perhaps be due to a third type of virus, as yet unisolated, and antigenically distinct from virus A or B.

Andrewes has postulated the existence of influenza viruses of various grades of virulence (see p 583), and it certainly appears that the clinical syndrome of influenza can be caused by agents of widely different pathogenicity to ferrets and mice. It can be suggested that an attack of influenza due to a virus of low grade virulence would not immunize against attack by a virus of virulence "stepped-up" by frequent transfer. It has been suggested that influenza virus may elaborate a toxin, and possibly this factor is of importance in determining the virulence of a strain (see p. 608).

As regards the host, it is generally agreed that practically every person becomes infected with the virus at a fairly early stage in their life Antibodies to the virus are rare in early childhood, but are almost universal in adolescence and adult life (see Ch. LXIII)

[illegible]

conferring immunity if the antibody is raised above a certain level (see p 669).

When a person with antibody in the blood becomes exposed to reinfection, it is probable that invasion of the superficial respiratory epithelium, i e, in nose, trachea, and perhaps bronchi, occurs. Circulating antibody cannot prevent this invasion, but it probably can limit the further spread of the agent The invasion of virus acts as a further stimulus to the production of fresh antibody.

The nasal secretion of certain persons contains a virus inactivating agent which is probably serum antibody (see p. 628) An agent like this could presumably protect superficial cells from invasion, and could limit spread of the virus from cell to cell.

Reinfection under experimental conditions is often associated with some symptoms in the upper respiratory tract, and it may be that these are allergic in character (see p 657), and represent the reaction of the sensitized tissues of the upper respiratory tract to the specific agent.

In animals, recovery from infection is associated with histological changes in the nose (ferret) or respiratory tract (mice). These changes appear to confer a certain degree of immunity to reinfection (see p. 655). It is not known whether such changes occur in man, but it seems possible.

In conclusion, therefore, it is evident that influenzal immunity in man is complex The presence of antibody in blood and nasal secretion is the most important factor as regards the host, allergy, and structural changes in the respiratory tract, may also be of importance. As regards the parasite, antigenic structure and virulence are the factors that determine its probable pathogenicity for any given person

HISTOLOGY

Hogan and Crawford (1942 *b*) suggest that the lesions in the cornea are in the nature of an acute dilatation and swelling of the corneal lymphatics, with edema of the affected tissues. Lymph spaces become filled with debris. In severer cases, there is actual destruction of tissue

Feigenbaum, Michaelson, and Kornblüth (1945) described a flattening of the corneal epithelium, marked capillary dilatation, and edema in the subepithelial tissue. There were subepithelial infiltrations with lymphocytes and large mononuclears Mitoses were seen. In chronic cases, hypertrophied papillae were present.

EPIDEMIOLOGY

Age incidence. All ages are susceptible, and cases have been seen in infants

Geographical incidence. The disease has a widespread distribution A number of severe outbreaks of the disease have been reported from India (Herbert, 1901; Kirkpatrick, 1920; Wright, 1930, Kirwan, 1935). It also occurs in Malay, Java, China, and Japan (see Bedell, 1943), and in Tasmania (Hamilton, 1942).

In Palestine, Feigenbaum, Michaelson, and Kornblüth (1945) studied nearly 400 cases The disease was most prevalent at the beginning of the rainy season. At first the cases were in coastal areas, but later were reported inland.

in the Second World War, mainly in shipyards and industrial plants, occurred in the San Francisco Bay area from September 1941 to January 1942 (Hogan and Crawford, 1942 *a, b*, Kuh, 1943). Portland (Oregon) was visited in November and December 1941 (Rieke, 1942). Cases were also seen in Seattle (see Bedell, 1943). Later, in 1942, cases were seen on the eastern seaboard in New York, Schenectady and inland (Perkins, Korns, and Westphal, 1943; Sanders and Alexander, 1943; Sanders *et al.*, 1943, Korns, Sanders, and Alexander, 1944) An outbreak in Detroit was described by Molner and Cooper (1944). The features of the disease in recent American outbreaks have been fully described by the above authors and other sources (Circular Letter No 14, 1943; *J. Amer. med. Assn*, 1943).

It se

riers frc

1941)

"Contrc

Occupational incidence. Although most of the recent American cases occurred in industrial workers, such as shipyard employees, many nonindustrial workers were affected It is probable that the conditions of work in industrial plants are often favorable to the spread of the virus of EKC The incidence of attack in industrial plants has usually been about 5 per cent.

Method of spread There seems little doubt that minor traumata, such as the presence of noxious gases or dust, predispose to infection. The disease may be spread by direct contact with conjunctival secretion, or by means of fomites such as soap, towels, and washbasins The infection may be passed through touching the hands of a sufferer, and transferring the infection to the eye by rubbing

Equipment used in examining and treating eyes may transfer the infection, and on no account should eye-droppers or brushes be returned to a bottle of lotion before being sterilized Physicians or nurses may inadvertently infect themselves unless vigorous handwashing is performed after attending to cases (see Allen, 1944).

SECTION 6. VIRUS INFECTIONS OF THE EYE

CHAPTER LXIV

EPIDEMIC KERATOCONJUNCTIVITIS

HISTORICAL

EPIDEMIC keratoconjunctivitis was *probably first described by German workers at* the end of last century (Fuchs, 1889; von Reuss, 1889, von Stellwag, 1889). Since then it has been reported from India, the Far East, Britain, America, and elsewhere. The clinical features of the disease are quite characteristic, and suggest an infective origin. Epidemic keratoconjunctivitis has for long been held to be a virus infection on general grounds, but only quite recently has a specific filtrable agent been described (Sanders, 1942; Sanders and Alexander, 1943).

It is probable that epidemic keratoconjunctivitis (EKC) is identical with a number of other conditions called variously. superficial punctate keratitis, keratitis subepithelialis, keratitis maculosa, and nummular keratitis. The condition known as Béal's conjunctivitis may be similar It is not, however, possible to be quite certain of the identity of these conditions with EKC, until virus studies have been carried out. We shall confine our description to the features, epidemiology, and etiology of "epidemic keratoconjunctivitis," which has all the characters of a specific infection, with particular reference to recent American experience. Full reviews of the literature are given by Hogan and Crawford (1942 *b*), Bedell (1943), and Rados (1944).

CLINICAL FEATURES

The incubation period of the disease is about 5–10 days.

There may be a short prodromal period characterized by malaise and slight pyrexia. The onset of conjunctivitis is sudden, and there is usually a feeling as if a foreign body is present. In fact, most patients seek attention for this complaint. There is hyperemia and edema of the palpebral and bulbar conjunctivae. The lids, chiefly the upper lid, are edematous The sclera is congested. There is usually a watery discharge from the affected eye, and photophobia. Pseudomembranes may form, usually in the lower lid, on removal these leave bleeding points Petechial hemorrhages may be found in the conjunctiva

The cornea is involved in 50–90 per cent. of cases, from 1–5 weeks after onset. *Discrete grayish infiltrates develop in the epithelial and subepithelial layers,* usually in the pupillary area The overlying epithelium is seldom ulcerated

A very characteristic feature is the presence of enlarged tender preauricular glands, sometimes other glands are involved also.

The disease usually begins in one eye, and in about half the cases the other is *involved after a few days, the disease tends to run a shorter* and milder course in the second eye.

EKC is of considerable economic importance, as sufferers are unable to work for some time Ocular sequelae, however, are unusual

Microscopic examination of the exudate shows the presence of mononuclear cells. No *definite inclusions have been seen Only the usual conjunctival* flora are found on bacteriological examination, sometimes the cultures prove sterile.

Laboratory diagnosis is made by inoculating tissue cultures or mice with conjunctival exudate or fragments of corneal tissue (see below)

5. The Virus of Sanders and Alexander

There seems little doubt, although the virus was isolated on only a few occasions, that the cause of the recent American outbreaks was a virus isolated by Sanders (Sanders, 1942, Sanders and Alexander, 1943, Sanders *et al*, 1943). The virus was isolated from conjunctival fragments in tissue cultures, and was adapted to mice Braley (1945) confirmed these observations Another strain of this type of virus was isolated by Maumenee, Hayes, and Hartman (1945).

Animals.

The virus can be passed to adult *mice* by the intracerebral or intranasal routes, or to unweaned mice by the peritoneal route (Sanders, 1942, Sanders and Alexander, 1943, Sanders *et al*, 1943, Braley, 1945). The symptoms develop after 48–72 hours, are not severe, and the animal usually recovers Virus is found mainly in the brain. Histological changes are slight

On intracerebral injection, Sanders' virus may produce sudden death on the 8th day in rabbits (Sanders and Alexander, 1943)

Feigenbaum, Michaelson, and Kornblüth (1945) isolated a virus similar to that of Sanders, and found that it produced opacities in the rabbit cornea 24–48 hours after inoculation which might persist for several weeks

Filtration and cultivation.

[illegible] -feld filter, it passes through mem- [illegible] through those of 50–75 mu APD [illegible] ichaelson, and Kornbluth (1945) also found the virus to be filtrable

Virus in conjunctival scrapings can be propagated in embryo mouse brain serum ultrafiltrate cultures (Sanders and Alexander, 1943, Sanders *et al*, 1943, Braley, 1945, Feigenbaum, Michaelson, and Kornbluth, 1945). Virus proliferates best at room temperature Transfers must be made with ground up cells. The presence of virus is shown by inoculating mice intracerebrally.

After inoculation in the allantoic cavity, the embryo died in 5–6 days. Passage can be continued and the allantoic fluid infects mice (Calkins and Bond, 1944)

Relationship to other viruses.

The virus appears to be specific, and Sanders and Alexander (1943) found that their agent was not neutralized by antiserum to LCM or herpes viruses Mice immunized against Theiler's virus were susceptible to EKC virus. EKC virus was not neutralized by hyperimmune rabbit antiserum to Theiler's virus

IMMUNITY

Active Immunity

There does not appear to be any significant degree of active immunity in man on recovery from infection

Mice recovered from infection with Sanders' virus showed some resistance to an intracerebral challenge (Braley, 1945)

Serum Antibodies

Virus neutralizing antibodies develop in convalescence, and are demonstrated by cerebral inoculation in mice (Sanders, 1942, Sanders and Alexander, 1943, Sanders *et al*, 1943, Korns, Sanders, and Alexander, 1944, Braley, 1945).

Antibodies can also be demonstrated by inoculating virus-serum mixtures on the scarified rabbit cornea (Feigenbaum, Michaelson, and Kornbluth, 1945), or in the allantoic sac (Calkins and Bond, 1944).

Infection in contacts and carriers It has been estimated that about 5 per cent. of household contacts develop the disease. There seems little doubt that carriers may exist, and the sera of such apparently healthy persons may neutralize the virus of EKC (Perkins, Korns, and Westphal, 1943; Korns, Sanders, and Alexander, 1944). Doubtless such persons suffer from a subclinical attack.

Control. Various official and other sources have described the methods of control to be followed (e.g., Circular Letter No 14, 1943; Heiman, 1943, *Publ. Hlth Rep*, *Wash*, 1943). The case must be isolated, and use individual soap, towels, and washbasin. He should be instructed not to rub his eyes, and to wash his hands frequently.

Special attention should be paid to the sterilization of protective goggles or eyeshields.

Medical and nursing attendants must use scrupulous care to avoid transmitting the infection, and wash their hands at once after attending to a case.

HUMAN TRANSMISSION EXPERIMENTS

The infection can be transferred to human volunteers by conjunctival instillation of infective material from a previous case (Wright, 1930).

Sanders' virus also produces infection (Sanders, 1942; Sanders and Alexander, 1943).

THE ETIOLOGY OF EKC

Various theories have been advanced to explain the etiology of EKC, and these are reviewed by Hogan and Crawford (1942 *b*). It is now accepted that the disease is caused by a virus, although more than one agent of this group has been isolated from cases apparently typical clinically

1 A number of workers has regarded herpes febrilis virus as the cause of EKC. For example, Maumenee, Hayes, and Hartman (1945) isolated a number of strains of virus that appeared to be herpes simplex from cases of clinical EKC. The strains produced nuclear inclusions in the corneal epithelium of the rabbit They concluded that herpes virus can cause a condition identical clinically with EKC

However, herpes cornealis is a well-recognized condition (see Ch. XVII), and would not appear to resemble EKC in any significant respect Herpetic infections seldom occur in the form of epidemics, and in adults the infection is usually recurrent, the initial infection having been contracted in infancy. Hogan and Crawford (1942 *b*) do not accept the herpes virus as etiological in EKC for the following additional reasons Vesicles are very rare in EKC, and there is no ulceration of the cornea. There is no constant corneal anesthesia in EKC. The majority of workers has failed to produce a typical herpetic keratitis with consecutive encephalitis in rabbits inoculated on the cornea with material from cases of EKC In EKC the lesions usually involve both eyes

2 Dresel, Weineck, and Meding (1941) implanted tissue from the cornea on the chorio-allantois, and found that the embryo was killed One strain of agent was passed a number of times

3 Gallardo and Hardy (1943) isolated a virus ("S") from a case of cicatrizing keratoconjunctivitis, characterized by progressive cicatrization and shrinkage of the conjunctiva, more marked in the lower than upper fornices, progressive pannus, and irregular vascularization S virus closely resembled vaccinia as regards EB's, inclusions and pathogenicity for the chorio-allantois, cross neutralization tests also showed the two agents to be closely related

4 Wright (1930) claimed to have found inclusions in the corneal tissue resembling Negri or Guarnieri bodies Wright also produced changes in the rabbit cornea resembling those found in man

CHAPTER LXV

TRACHOMA

Trachoma was recognized as a disease by the ancient Greeks and Romans, being referred to by Celsus as *aspritudo* and by Dioscorides as τράχωμα (roughness).

In 1907, Halberstaedter and Prowazek discovered intracellular clumps of minute bodies in tissue scrapings derived from cases of trachoma studied in Java and, although these workers (see Halberstaedter, 1912) claimed that the structures they had found were the etiological agents of trachoma, little attention was paid to the subject at the time In 1927 interest was focused upon the claims of Noguchi (1928), who maintained that the organism he had isolated from cases of trachoma and named *B. granulosis* was the cause of the disease Subsequent investigation into the rôle of *B. granulosis* proved that Noguchi had been mistaken and that the organism was unrelated to the condition. Within the last decade studies on the morphology of psittacosis virus and the virus of inclusion conjunctivitis have renewed interest in the claims of Halberstaedter and Prowazek, since the inclusions found by them in trachoma are very similar to those occurring in psittacosis and inclusion conjunctivitis Modern work has established that trachoma is a virus disease and that the Halberstaedter-Prowazek (HP) body is the primary infective agent.

The virus bears morphological resemblance to those members of the pneumonitis-psittacosis group to be discussed in the next section, but differs from these agents in several important respects. It is most closely related to the virus of inclusion conjunctivitis, and the two agents form a biological group of their own.

The disease has always attracted much attention in the literature, and general reviews are those of Stewart (1939) and Bland (1945).

EPIDEMIOLOGY

Geographical Distribution

Trachoma occurs irregularly throughout the world. In some parts, such as Egypt, Palestine, the Levant, Algeria, Mo[illegible]
Corsica, Cyprus, certain areas of Rus[illegible]
Malaya, and Polynesia, its incidence is [illegible]
Latvia, Estonia, Poland, Lithuania, Finl[illegible]
Mexico, the Argentine, and Brazil it affects only certain sections of the population. In other countries, such as Ireland, Belgium, Holland, France, Spain, Portugal, Austria, Hungary, Germany (East Prussia), Bulgaria, Yugoslavia, Albania, Roumania, the United States, Canada and Australasia it only involves a few localities. In the United States and Canada the disease is more common in the Indian populations (Wall, 1934), Gradle (1939) estimated that there were over 30,000 cases in whites, and 25,000 in Indians in the United States The disease has been recorded [illegible]

[illegible]

cludes with the remark that "It would not be too much to say that the stigmata of the disease, active or cured, are borne by half the inhabitants of the globe. All nationalities seem to be equally susceptible to the disease, but Howard (1933 *a*) states that the Negroes in Missouri are more resistant than the whites. Scott alludes to the mild infection seen in the West African Negro (1945).

In some countries the disease is a rare affliction, being seldom seen in Britain,

No neutralizing antibodies can be detected in the first week, but after 6-10 weeks, the sera of all convalescents show antibodies, and these may persist for some months.

Rabbits can be hyperimmunized with the production of potent virus neutralizing antisera.

SPECIFIC TREATMENT

Sulfonamides and penicillin have no effect on the virus (Braley, 1945). Convalescent plasma or serum given before the 5th day of illness is the treatment of choice (Braley, 1945).

tricial tissue forms, engulfing within its interstices the small islets of diseased conjunctival tissue, which gradually become compressed by the contracting fibrous tissue bands. Corneal pannus is evident at this stage when seen either by the naked eye or with a corneal loupe Thickening of the tarsus, trichiasis, and entropion may also develop as terminal sequelae. The clinical manifestations seen in *Tr IV* represent the final picture after the disease has run its course. Here the normal epithelium has been replaced by fibrous tissue, and likewise the subepithelial infiltration has

choma is to be found in the publications of Cange, Foley, and Parrot (1935), Cange and Foley (1924), and Julianelle and Smith, (1943)

MORBID ANATOMY AND HISTOLOGY

It is generally agreed that the principal lesion in trachoma is primary subepithelial lymphoid infiltration with lymphocytes and plasma cells, followed by degenerative

states that the primary

llicle only a secondary

of conditions prevails,

he believes that trachoma is an inflammatory and not a hyperplastic disease.

clusions upon 5 laws which have sometimes been referred to as the *laws of true trachoma*, namely: (1) that true trachoma does not exist without germinal centers or follicles; (2) the true trachoma follicle is a lymphoblasto-endothelial formation which is either confluent or follicular, (3) true trachoma develops in the most vascular part of the conjunctiva, namely the fornix cul-de-sac and the limbus, (4) true trachoma ends by degeneration, cicatrization, or hyalinization, and lastly (5) the true disease can recur after healing, but is always accompanied by the formation of fresh follicles. Pascheff, therefore, concludes that trachoma is due to hyperplasia of lymphatic structures of the conjunctiva, and is, in consequence, a lymphadenoid

processes is as yet imperfectly understood, but in the second, the formation of cicatricial connective tissue originates chiefly in the cells of the bloodvessel walls. The localization of infection in the tarsal conjunctiva expresses itself mainly in submucosal proliferation, which may develop into a massive adenoid structure with follicles

The

(1937),

tissue followed by involvement of the tarsus itself Peters (1932) has described lattice-shaped fibers which participate in the process of fibrosis, and Busacca (1933, 1934 *a*, 1935) has made a special study of Herbert's pits in trachoma. Krueckmann (1933) has drawn attention to a trachoma-like condition of the nasopharynx, and Charlin (1934) has pointed out the existence of latent trachoma The incidence of dacryocystitis in trachoma has been investigated by Aliquò-Mazzei (1937), who found it to be 4 21 per cent Milton and Beattie (1942) have also studied the histology For details regarding the biomicroscopical appearances of the limbic region, see Galante (1934), Chirkovskiy and Dymshits (1934), and Thygeson (1934 *b*).

Norway, Sweden, Denmark, Iceland, Switzerland, and New Zealand. In Britain it is a practically unknown condition, with the exception of Glasgow, and London (Sorsby, 1939); in both cities the disease is on the decline. Further information regarding the world distribution of trachoma is to be found in the *Report of the Health Organisation of the League of Nations* (1930), no. C H. 822 (1), and also in the publications of Mackenzie (1935), McMuller and Rice (1934), Tiong (1932), Busacca (1934 *b*), Cattaneo (1934), Marquez (1934), Marin-Amat and Torres (1934), Rostkowski (1934), and Stones (1939).

Susceptibility of Children and Social Factors Concerned in the Dissemination of Trachoma

Young children are very susceptible to trachoma Massoud (1935), in referring to trachoma as an endemic disease of Egypt, states that it is usually acquired in early infancy and its dissemination is fostered by errors of diet, hygiene, and other factors calculated to reduce vitality.

Bruck (1936) found that in Palestine 75 per cent. of the cases occurred in children less than 3 years old; among Fijian natives, likewise, the majority of cases developed during childhood (Stuppel, 1933), and many schoolchildren, for example, showed complete cicatrization of the conjunctiva. Sedan (1937) also alluded to the extreme readiness with which infants developed trachoma and emphasized the part played by the neglect of personal hygiene, and the evil of poverty in the spread of infection Motais (1932) quoted cases in which European children contracted the disease from their native nursemaids, while Massoud (1937) asserted that children with enlarged adenoids were highly susceptible to infection (see also François, 1935)

CLINICAL FEATURES

Onset. The condition commences with the formation of a number of rounded or irregularly shaped, solid granules of a pale yellowish-pink color, at the upper fornix. This is accompanied by clouding of the vision, especially in the mornings, but without change in the cornea. Later, translucent grayish-white round formations about the size of a millet seed develop in the deeper layers of the tarsal conjunctiva of the upper lids, and these have been regarded as a specific feature of trachomatous conjunctivitis. Occasionally there is also interference with the functioning of Muller's superior tarsal muscle, the eyelid tends to droop, and the patient's eyes present a sleepy appearance (see Falta, 1932).

The course of the disease has been arbitrarily divided by MacCallan (1936 *a*, *c*)

(3) the appearance of papillary hypertrophy, and lastly, (4) the stage of fibrous tissue formation These features contribute a basis for the classification of trachoma given below *MacCallan's classification* has been adopted universally by ophthalmologists as a sound working hypothesis for clinical description

Tr I is applied to the stage at which tiny follicles develop, or else generalized subepithelial infiltration occurs, imparting to the conjunctiva a red and velvety appearance. Rarely, these lesions may heal spontaneously, leaving behind them no trace of damage, but more freque [illegible] The second phase of the disease is characteri [illegible] cences, in which case it is called T [illegible] trophy resulting from superimposed bacterial infection, and it is designated [illegible] Conjunctival secretion is usually present at this juncture and the illness may last an indefinite period *Tr III*, which succeeds either stage *Tr I* or *Tr II*, represents the stage at which partial cicatrization or cure may occur, and a network of cica-

investigators, who also proved the contagious character of the disease. Certain cases of special interest illustrating the nature of trachoma have been reported in the publication of Cuénod and Nataf (1933), who have quoted 3 instances in which ophthalmic surgeons contracted the disease from their patients, and of Zentmayer (1934), who described the spread of infection among wrestlers in America. Other cases of interest are those recorded by Roshchin (1934) who mentions that in 11 cases of trachomatous pannus treated by him by the Dernig flap operation, the mucosa from the lip which was grafted on the surface of the conjunctiva later became invaded with trachomatous follicles.

THE RÔLE OF *B. GRANULOSIS* IN TRACHOMA

Evidence in Favor of *B. Granulosis* as the Causal Agent of Trachoma

In 1928 Noguchi recovered this organism in semisolid *Leptospira* medium from 5 cases in American Indians Colonies occurred as small grayish-white structures, the organism appeared as a motile bacillus possessing a single flagellum, and measured about 0.3 μ in its longest diameter, it was usually *gram negative*, although Trapesontzewa (1932) maintained that it varied in its reaction to Gram's stain. About 100 monkeys were used by Noguchi for inoculation experiments, and, according to Robbins (1935), several ophthalmologists who examined the animals expressed the opinion that the disease closely resembled human trachoma.

Noguchi's observation was soon confirmed by subsequent workers, all of whom were able to produce a granular form of conjunctivitis in monkeys by inoculating them with cultures of *B granulosis* isolated from cases of trachoma, and, among others, the following have recorded their results in the literature Tyler (1929), Olitsky, Knutti, and Tyler (1931), Reimann and Pillat (1931), Wilson (1931), Finnoff and Thygeson (1931), Bengtson (1932 *b*), Proctor, Finnoff, and Thygeson (1932), Thygeson (1932), Tallo (1932), Weiss (1933 *b*), Olitsky (1934).

These researches were repeated by other workers. Thus, in the *United States* it was observed by Tilden and Tyler (1930), Kendall and Gifford (1930), Olitsky, Knutti, and Tyler (1931), Finnoff and Thygeson (1931), Thygeson (1932), and Weiss (1933 *c*) In *Italy* by Bordonaro (1929), Addario (1930), Bietti (1930), and Tallo (1932) In *Tunis* by Weiss (1933 *c*) and Thygeson (1933 *a*) In *Egypt* by Olitsky, Knutti, and Tyler (1931). In *Russia* by Berberov and Alekseev (1932) and Trapesontzewa (1936) In *Hungary* by Kanyó and Rotth (1932). In *China* by Reimann and Pillat (1931) In *Japan* by Takamatsu (1932). In *Scotland* by Meighan and Urquhart (1936).

Certain observers considered that conjunctivitis reproduced in monkeys resembled the lesions of human trachoma, but Thygeson (1932, 1933 *b*), for instance, pointed out that the two were not identical, since cicatrization and pannus were absent in the monkey Furthermore, another objection was raised on the ground that monkeys sometimes suffered from spontaneous follicular conjunctivitis, but, according to Weiss (1933 *a*), this condition was different from that produced after experimental inoculation with *B granulosis* Some writers suggested that inability to reproduce typical trachomatous lesions in monkeys might have been due either to natural resistance or to loss in virulence of the cultures (see Meighan and Urquhart, 1936)

Failures to Isolate *B. granulosis* from Cases of Trachoma

Among other workers, the following have reported that they were unable to find *B granulosis* in cases of trachoma investigated by them in different parts of the world the *United States* (Bengtson, 1932 *a*), *Tunis* (Thygeson, 1931), *Egypt* (Wilson, 1931), *Roumania* (Puscariu and Nitzulescu, 1932), *Poland* (Lawrynowicz and Melanowski, 1930), *China* (Tang, 1930, 1934), *Germany* (Rohrschneider and

Cytology of the Conjunctival Secretion

This has been studied by Marcus and Wainer (1936), who point out that the results of such examination assist in the differential diagnosis of trachoma from follicular conjunctivitis. Thus, in the former it is common to find embryonal forms of lymphocytes with vacuolated protoplasm and nuclear mitoses, the so-called "shadow cells" of Humprecht resulting from cytolysis of these elements, and epithelial cells exhibiting degenerative changes of their nuclei. In follicular conjunctivitis, however, embryonal cells are absent, histiocytes are rare, the epithelial cells are normal in their appearance, and eosinophils are commonly present.

CLINICAL PATHOLOGY

The *lysozyme content* in normal tears has been compared with that found in the lacrimal secretion derived from 64 cases of trachoma by Mourzinn and Souchkowa (1935). These workers showed that the titer was considerably diminished during the acute stages of trachoma and particularly so in those cases in which corneal ulceration existed. There was a tendency for the lysozyme content gradually to return to normal as healing occurred.

The *blood picture* in trachoma has been investigated by François (1931), who found that in chronic cases a neutropenia existed accompanied by a relative lymphocytosis and monocytosis. Mihail (1936) made a similar reference to the blood picture and observed that monocytes were more numerous than lymphocytes, and that no eosinophilia occurred without concomitant parasitic infection.

INCUBATION PERIOD OF TRACHOMA

In the case of the naturally acquired disease the incubation period cannot always be estimated accurately. MacCallan (1936 *c*) points out that the onset of the disease is usually insidious and symptomless, so that the exact period is diffiult to assess.

On the other hand, in the experimentally induced disease the incubation period is comparatively brief, and from the results of tests performed on human volunteers it was found that
and Vancea (1932)
days by Delanoe (
mental trachoma is usually an acute illness from the start, characterized by a short incubation period, whereas the natural disease is slow in its onset and chronic from the beginning (see Michail and Vancea, 1932; and Howard, 1933 *a*) This fact was appreciated as long ago as 1900, and Halberstaedter (1912) mentions that, when Addario first announced that the incubation period of the experimental disease in man was 3 to 6 days, Greeff, Frosch, and Clausen (1908) repeated the work because Addario's results were contrary to the opinion current at the time (see also Addario, 1910).

To-day these facts are well established, and the incubation period of experimentally induced trachoma is accepted as being of shorter duration than the naturally acquired condition At the present time there is a growing tendency among a section of writers (see Foley and Parrot, 1937 *a*) to regard the virus of trachoma as one possessing feebly invasive properties If this assumption is proved to be correct, it may be argued that the clinical differences existing between naturally and artificially acquired trachoma are explicable on the grounds that a greater quantity of virus is implanted into a susceptible conjunctiva by direct injection than is possible in natural contagion

INFECTIVITY IN MAN

Addario in 1900 was the first to reproduce the disease in human volunteers by inoculating the conjunctivae with tissue scrapings derived from the eyelids of trachomatous subjects, and this work was confirmed by Greeff (1909) and other

The preparation of films.

The secret of success in preparing films lies in the art of removing as many epithelial cells as possible from the conjunctival surface In order to accomplish this, the eyelid should be everted, freed from pus by washing it with salt solution, and the surface scraped with a single stroke of a small knife, taking care to cause as little bleeding as possible. The epithelial scrapings are now placed on a clean glass slide and spread evenly over its surface with the aid of another glass slide, after the usual manner of preparing a blood film, exerting only the minimum amount of pressure when so doing. Films prepared by rubbing a platinum loopful of conjunctival secretion on the surface of a slide must not be used when attempting to demonstrate inclusion bodies, likewise cotton wool swabs are unsatisfactory for this purpose.

Staining by Giemsa's method.

Fixation. Preparations are dried in air, treated with either methyl alcohol, absolute alcohol, or a mixture of equal parts of absolute alcohol and ether for 10 minutes and then dried with blotting paper.

Staining. A freshly prepared solution of Giemsa's stain is required

12 parts Giemsa's eosin solution, consisting of 2.5 c c. of 1 per cent. French eosin solution to 500 c c of distilled water.
3 parts azure I (diluted 1 in 1,000).
3 parts azure II (diluted 0 8 in 1,000)

Procedure The fixed preparations are immersed for 6 hours in the solution, removed at the end of that time, rinsed with water and dried with blotting paper The method has given excellent results and was originally recommended by Halberstaedter and Prowazek (1907 *a*, *b*, 1909, 1910), and Greeff, Frosch, and Clausen (1908) Various modifications of this method have been used with equal success by other workers

Greeff (1909) stained for from 6 to 9 hours at a temperature of 37° C, or with the same mixture for 3 hours at 56° C.

Herzog (1909, 1910) employed a 1 in 40 dilution of commercial Giemsa's solution in distilled water and stained the films with it for 1½ hours at 37° C

Heymann (1909, 1910) preferred to use a 1 in 20 dilution of the same stain applied for ¾ hour at room temperature, and Bertarelli and Cecchetto (1909) employed a 1 in 11 dilution for 24 hours

Lindner (1910 *a*) advocated the employment of 2 methods which accentuated the basophilic nature of the inclusion bodies, films were dried in air and fixed with absolute alco[illegible]
procedures [illegible]
of 10 c c. of [illegible]
acetic acid f[illegible]
solute alcohol, and examined under the microscope. Method B consisted of staining the slide for 10 minutes in a solution consisting of 10 drops of Giemsa's stain mixed with 10 drops of 0 5 per cent acetic acid, after which it was washed with distilled water, dried in air, mounted in cedar-wood oil, and examined as usual In preparations stained by these methods, the inclusion bodies, the granules of mast cells, and contaminating bacteria stained blue, the nuclei of lymphocytes and leukocytes also [illegible] than the [illegible] intensely

Sections can also be stained in this way Tissue is fixed in sublimate or formol Sections are stained for 12 to 48 hours in the solution employed in method A, immersed in distilled water for ½ to 1 hour, dehydrated with absolute alcohol and xylol, and mounted in cedar-wood oil. An alternative procedure is to stain with

Heymann, 1931), *France* (Lumbroso and van Sant, 1931; Morax, 1930); and *England* (McCartney and Mayou, 1930).

Negative Results following Experimental Inoculation of Man

Cultures of *B. granulosis* have been injected into the conjunctivae of blind persons, but we are unable to quote a single instance from the literature in which typical trachoma was reproduced by this means. In a few cases a transient and mild inflammatory type of conjunctivitis ensued following inoculation of the organism, but, apart from such a response (which is only to be expected if living bacteria are injected into healthy tissues), true trachomatous cicatrization and pannus have never been produced by *B. granulosis* (see Proctor, Finnoff, and Thygeson, 1932, Thygeson, 1933 *a*, *b*, Candian, 1933; Lindner, 1929; Howard, 1933 *b*). Berberov and Alekseev (1932) inoculated the eyes of children but the organism failed to reproduce the disease, thus conclusively proving that *B. granulosis* is not the cause of human trachoma (see also Thygeson, 1932, 1933 *a*, *b*, Wilson, 1931; Robbins, 1935).

The Rôle of *B. granulosis* Investigated Serologically

[illegible] to Weiss (1933 *c*), the sera of [illegible] *granulosis* more frequently tha[illegible]ment fixation reactions, in which the organism was used as antigen against the patient's serum, have also been described by Trapesontzewa (1937). On the other hand, Fischer-Ascher (1931) failed to secure either positive complement fixation or agglutination reactions in his experiments, and Trapesontzewa (1932) reported negative agglutination tests between the organism and human serum Mikaelian (1931) likewise obtained negative skin tests after injecting emulsions of *B. granulosis* intradermally.

Conclusions

The divergence of opinion suggests that *B. granulosis* is not the primary etiological agent, but is more probably a secondary invader Investigations by Harrison and Julianelle (1936) revealed that the bacterial flora of the eye in trachoma was in no way different from that of the normal conjunctiva Under the circumstances, it must be concluded that, so far, it has not been possible to isolate any specific organism from cases of human trachoma, or to reproduce the disease in man by the injection of *B. granulosis* or any other bacterium.

THE INCLUSION BODIES OF TRACHOMA

It is generally agreed that the Halberstaedter-Prowazek inclusion bodies found within the cytoplasm of the superficial epithelial cells of the conjunctiva are most numerous during the acute stages of trachoma For example, Rotth (1932) stated that they were noticed by him in practically every case during the early stages of the illness, but as the condition progressed they became less frequent, and in patients who had suffered for over 5 years, they were found in only 50 per cent of persons examined

MacCallan (1936 *b*) also alluded to the same point, mentioning that inclusion bodies were commonly found in the first stage (*Tr I*) of trachoma and that in the later phases of the condition they became scanty in stained films In Japan Onisi (1936) found that inclusions were most numerous in patients who lived in the south of the country.

Staining of the Halberstaedter-Prowazek Inclusions of Trachoma

Halberstaedter's (1912) classical account of the methods employed for staining these inclusion bodies, contained in Prowazek's *Handbuch der Pathogenen Protozoen*, is as yet unsurpassed

dumb-bell. Pear-shaped and hourglass-like forms have also been observed, and these are best demonstrated in wet fixed films which have been treated with Heidenhain's iron hematoxylin stain (Leber and Hartmann, 1909).

Large inclusion bodies.

These usually appear in the cytoplasm of infected epithelial cells, but according to Leber and Hartmann have been detected in the nucleus.

Clumps of elementary bodies.

These are often found in the cytoplasm of epithelial cells, and may be small in size or else they may form a large compact mass lying free in the cytoplasm or clinging to the surface of the nucleus Alternatively, the elementary bodies may be so numerous as to fill completely the cytoplasm of the cell and, less commonly, they may appear evenly distributed throughout the cell, each elementary body being embedded in a pale blue-staining mass of protoplasm referred to by Halberstaedter (1912) as "plastin-like"[1] material, to which we shall make repeated references in the text. The following is a translation of Halberstaedter and Prowazek's classical account of the inclusion bodies of trachoma studied in Java:

"In the Giemsa preparations, dark blue-stained nonhomogeneous irregular inclusions were visible beside the nucleus in the pale blue protoplasm of the epithelial cells. The inclusions were at first small, round or oval in shape but they gradually grew in size and finally assumed the appearance of a mulberry During this process the inclusion, commencing from its center, became less dense in character. Gradually the inclusions tended to clasp the nucleus like a cap and later fine red-stained corpuscles appeared within these inclusions, and as they rapidly multiplied the blue masses disappeared simultaneously. Finally the granules or corpuscles (*elementary bodies*) occupied the greater part of the protoplasm and then the blue-stained substance only became visible as small islands between the mass of granules. In smear preparations, free granules were also found extracellularly.

"The changes described in human conjunctival epithelium could be transferred from man to the orang-utan and also from one ape to another by experimental inoculation. The blue amorphous masses of the inclusions had the same affinity for the blue component of the Giemsa dye as the nucleoli and were probably identical with plastin The circumscribed granules, on the contrary, which were distinctly red and approximately 0 25 μ in size, probably represented the virus itself, for they multiplied rapidly by growing and then dividing into two colon-like granules"

The initial bodies of Lindner.

These bodies have been described in great detail by Lindner (1909 *a*, *b*, 1910 *a*, *b*), subjected to repeated investigation by later workers, and have been observed not only in the cytoplasm of epithelial cells in trachoma, but also in inclusion conjunctivitis of the newborn child (see p 718). Lindner and others have regarded them as the initial forms of the virus from which the elementary bodies are developed

and multiplies by repeated division to form groups and clusters of initial bodies which become embedded therein As growth proceeds, minute red-staining elementary bodies commence to appear inside the initial bodies, this process starts in those occupying the middle of the inclusion body mass, so that, after a time, the center of the inclusion cavity becomes filled with elementary bodies, and only a few initial bodies remain at the periphery of the cell Later, elementary bodies begin

[1] The reason for adoption of the name "plastin" does not appear to be very clear to us, but we have given prominence to it in our account since it indicates that those who observed its presence recognized that, following the entry of a virus, the cell was liable to react against the invader

a solution of 2 drops of Giemsa stain added to 15 c.c. of distilled water for 2 to 3 days, and then dehydrate the preparation with acetone, acetone-xylol, and xylol

Flemming (1910) first treated the film with old Giemsa solution for 5 hours, then carried out differentiation with a solution of absolute alcohol and 1 per cent. acetic acid, watching the preparation continuously under the microscope until nothing but the cell nuclei and trachoma inclusions remained visible. The former appeared a reddish-violet hue and the latter blue or red in color, depending on the stage of their development. For other methods of staining the inclusion of trachoma, see Bertarelli and Cecchetto (1909), and Botteri (1912).

Staining by Heidenhain's hematoxylin.

Heidenhain's iron hematoxylin stain has been highly recommended by Leber and Hartmann (1909).

Fixation Wet film preparations are treated with sublimate, alcohol, or Hermann's fluid.

Staining. Heidenhain's hematoxylin stain is applied for 24 hours.

The appearances of the elementary bodies when stained by this method are described by Leber and Hartmann as being deep black in color; the cytoplasm of the cell is light gray. The same method was employed by Herzog (1910) and Radziejewski (1909), both of whom recommended it, the former advocating its suitability for staining sections

Method of demonstrating inclusion bodies in sections.

Embedding of tissue.

1. Excise small fragments of tissue from the conjunctiva.
2. Fix in 3 per cent. sublimate alcohol containing 3 per cent. acetic acid
3. Heat to 50° C. for 1 hour.
4. Rinse in water.
5. Treat with dilute alcohol, absolute alcohol, and finally iodized alcohol for 1 hour.
6. Remove iodine with absolute alcohol
7. Treat with aniline oil, and fresh xylol several times.
8. Embed in soft paraffin for 1½ hours, and next in hard paraffin
9. Cut sections less than 5 μ in thickness, and mount on glass slides

Staining.

1. Dilute Weigert's hematoxylin solution to half strength and apply for 2 to 3 days.
2. Differentiate the slide in 1.5 to 4 per cent. iron alum solution, or in 30 per cent acetic acid, until the chromatin of the epithelial cell nucleus retains a distinct hematoxylin color, wash, dry, mount, and examine as usual

Morphology of Inclusion Bodies

Single granules.

In films stained by Giemsa's method (described above) prepared from conjunctival secretion in an acute case of trachoma, discrete extra- and intra-cellular granules can be detected These were referred to as "chlamydozoa of trachoma" by Prowazek (1907). They stain reddish in color and were subsequently renamed "elementary bodies" or "elementary organisms" by Herzog (1909), and are now recognized as being identical in morphology with the elementary bodies found in other virus diseases In size these minute particles measure 0.25 μ in diameter, and are surrounded by a halo of nonstaining material (the significance of which will be discussed later), they are frequently present in pairs, and are sometimes connected by a slender filament so that the whole structure resembles the outline of a

being present In sections, encapsulated bodies are found in the superficial epithelium, but not in the deeper layers. He also found granular inclusions in recticulum cells in the subepithelial layers

The Interpretation of the Trachoma Inclusions

The histological appearances presented in stained films and sections described above are difficult to explain owing to the number of possibilities which have to be considered Thus, it is conceivable that all the different types of inclusion body mentioned may represent a life cycle of changes exhibited by the parasite during the course of its development. On the other hand, it is possible that some of the inclusions may be forms of the living parasite, and others the reaction of the invaded cell towards it. A combination of these 2 factors is also likely to account for the so-called intermediate varieties mentioned. In discussing this problem Halberstaedter (1912) has suggested that the complete inclusion body might be constructed of 3 entirely different parts, the first of these is the blue-staining so-called "plastin-like" substance which Halberstaedter believes is a derivative of the cell cytoplasm, the second the red-staining parasite which appears as a clump of granules, and the third, a structureless matrix in which the elementary bodies are embedded The last-named component is of particular interest because it suggests that the elementary bodies do not lie free inside the inclusion body cavity, but are embedded in a gelatinous medium. Halberstaedter believes that it is the presence of this substance surrounding the elementary body which gives rise to the clear halo of nonstaining material sometimes evident in Giemsa-stained films He con-

scribed as plastin, on the contrary, is deposited on the elementary bodies which it covers like a shell, and its amount may either be plentiful, in which case it appears as coarse clumps, or else it may be sparsely distributed According to the same authority, the plastin substance not only represents the "defensive mechanism" of the host cell, but is also used by the elementary bodies as a nutritive medium,

Halberstaedter's conception of the composition of inclusion bodies of trachoma, based on a study of stained films, is of considerable interest to the authors, since,

of trachoma

The authors have observed the halo or nonstaining zone which sometimes surrounds individual elementary bodies in Giemsa-stained film preparations, and are in complete agreement with Halberstaedter's opinion that this clear area is formed

r their libera-

(1937 a), and

Foley and Parrot (1937 a) supports the contention that the inclusion bodies of trachoma represent a living virus and are not inanimate cell products The possibility of trachoma being an infection due to the symbiotic combination of a virus with a bacterium has been discussed by Thygeson (1934 c) and Pittaluga (1934) The following are some of the other opinions expressed on the trachoma inclusion

to develop inside the marginal initial bodies, until eventually all of these disappear and the cell becomes packed with elementary bodies.

Initial bodies have been observed by Lindner to occur not only in film preparations, but also in stained histological sections, and the following different shapes have been recognized. *ring forms* appearing as little *disks* stained at their edge, *diplococcus-like varieties* exhibiting polar staining, *oblong types*, being either rod-shaped in outline or else possessing a lateral curvature, and also *sickle-shaped forms*, all of which have been seen to occur not only as intracellular inclusions but also as free extra-cellular bodies. Thus, *free-lying initial bodies* have been described by Mijaschita (1908), Botteri (1912), and Thygeson (1934 *a*), but Stewart (1934), failed to find them in 300 cases examined in Egypt.

The residual bodies (*Restkörpter*) of Halberstaedter and Prowazek

These are found inside the cell inclusion alone, and stain red with Giemsa, or blue by Mallory's method In size residual bodies seem to be larger than the initial bodies, but as the elementary bodies become more numerous in the cell, they diminish in size correspondingly. Lindner believed that the residual body was not a growth phase of the virus manifested during the course of its development, but a nuclear fragment, basing this statement on the fact that since the residual body only occurred at one part of the inclusion body and could be stained with methyl green, it was unlikely that it was a living organism.

Plastin-like masses.

Amorphous masses appearing within the cytoplasm of parasitized cells have been referred to by Halberstaedter (1912) as plastin-like masses They are stained blue with Giemsa's solution and, since they show the same affinity for this dye as do the nucleoli of cells, it has been suggested that they are degenerative products (e g, by karyorrhexis) of the cell and not associated with the parasite.

Intermediate varieties of inclusion body.

Although the various forms of inclusion body already mentioned have been described as sharply defined structures, it is obvious from a survey of the literature that a multitude of intermediate varieties, which cannot be placed in any distinct category, exist. Whether or not these represent distinct phases of the parasite itself, or are made up of a combination of some of the forms described, it is impossible to tell, but Herzog (1909, 1910) has described one variety of inclusion body which can be assigned to the latter class This cytoplasmic inclusion consists of 2 components, the one a clump of red-staining elementary bodies and the other a thin blue envelope which surrounds them, so that the pink elementary bodies shining through the blue covering impart a purple tinge to the whole structure, and it was to describe this outer covering or "mantle" (χλαμύς) that Prowazek originally coined the term *Chlamydozoa*

Microchemical Properties of the Inclusions of Trachoma

Rice (1936) has made a series of interesting observations on the color reactions exhibited by the Halberstaedter-Prowazek inclusion body after treatment with iodine and other chemical reagents, from which he concluded that its outer surface is composed of carbohydrate material (see also Thygeson, 1938 *a*, Thygeson and Richards, 1938)

Later Observations

A number of later workers has studied HP inclusions (Braley, 1940, Julianelle, 1940 *a*, *b*; Loewenstein, 1945) Julianelle (1940 *b*) reports that tissues with inclusions are twice as infective for monkeys as tissues without Loewenstein (1945) reports that in scrapings the inclusions are polymorphic, individual EB's and inclusions

in the literature that occasionally volunteers who had been experimentally inoculated with infective material sometimes failed to develop the disease. This would appear to suggest either that such persons were immune to trachoma or else that, before the virus was able to establish itself in the healthy conjunctiva, a certain amount

the filtrate it usually proves to be nonpathogenic (see Thygeson and Proctor, 1935).

Experiments using Collodion Membranes

In 1934, Thygeson concluded that the Halberstaedter-Prowazek inclusion bodies and elementary bodies of trachoma represented intracellular colonies of a virus in different stages of its development. He moreover showed that these bodies could be concentrated by high-speed centrifugalization, and were small enough to traverse the pores of a collodion membrane filter possessing an average pore diameter of less than 0.2 μ.

Later, *Thygeson and Proctor (1935) further investigated this problem, and* again proved that the virus of trachoma was readily filterable through collodion membranes. In their experiments fresh trachomatous tissue was removed from 14 cases occurring in American Indians, suspended in broth of pH 7.6, clarified by passage through filter paper, and then passed through a collodion membrane 0.3 mm thick (possessing an APD of 0.75 μ), at a negative pressure of 150 mm. of mercury applied for 5 minutes Filtrates obtained by this method were free from bacteria, and 2 weeks after inoculation into the conjunctivae of 5 African sphinx baboons, typical trachomatous follicles developed at the site of injection Similar lesions were produced in baboons inoculated with unfiltered material.

Preservation

The virus dies rapidly outside the human body and, as yet, no method has been devised by which the infectivity of material can be preserved for any lenth of time.

There has been some divergence of opinion with regard to the exact length of time that the virus survives outside the body, but data based partly on human test inoculations and partly on animal results, as a whole suggest that the virus is readily destroyed. Table 30 shows a summary of findings obtained by different workers Julianelle and Harrison (1938) were able to preserve the infectivity of material for 7 days by suspending the tissue in veal infusion broth of pH 7.6 followed by storing it in an ice-chest at 4° C. In 50 per cent glycerol it remained active for 2 weeks, and Julianelle and Harrison (1938) showed that it was able to resist alternate freezing and thawing 16 times.

Trituration

Mechanical grinding and emulsification of trachomatous tissue in saline have no effect on the viability of the virus, according to Stewart (1933, 1934), and Julianelle and Harrison (1938).

Desiccation

According to Hess and Romer (1906), dried material lost its infectivity after 4 weeks, and Botteri (1912) found that material desiccated for 1½ hours at 15° C. lost its infectivity for baboons Nicolle, Cuénod, and Blaizot showed that drying for 30 minutes at 32° C. inactivated the virus Likewise, Julianelle and Harrison proved that infective material suffered considerable loss of pathogenicity when maintained in the desiccated state for a few days.

Flemming (1910), for example, denies the existence of any developmental forms of the parasite, and distinguishes 3 separate types of inclusion, namely, Type I, corresponding to the initial forms, Type II, the small cap-like inclusions with plastin still adherent to them, and lastly, Type III or fully developed bonnet-like inclusions composed of elementary bodies. Gruter (1938) does not think that these structures are virus bodies, but maintains that the Halberstaedter-Prowazek inclusions are simple spherical Golgi bodies which have increased in size through repeated cell division under the stimulus of inflammation, further, during the course of the trachomatous process he has not detected any structures simulating parasitic organisms. Stewart (1934) states that "the Halberstaedter-Prowazek inclusion body is a phagocytic vacuole in an epithelial cell. It may contain any microorganism which is present in the conjunctiva either bacterial or granular." In the same paper Stewart severely criticizes earlier work on the subject. Thygeson (1934 *a*), on the other hand, has contradicted the findings of Stewart, and asserts that the inclusions of trachoma are not phagocytosed bacteria, but typical intracellular forms of a filterable virus which exhibits different stages in its development

PROPERTIES OF THE TRACHOMA VIRUS

Filtrability

Attempts to show that the infective agent of trachoma belongs to the group of so-called filter-passing organisms have in the majority of experiments yielded negative results For the convenience of the reader, we have summarized the results of different workers in Table 29, and from these it will be observed that, while a few persons have been successful, many have failed to show that the virus is capable of traversing
nonpathogenicity of
the principal one bei
Certain workers have maintained that the virus is one which is only capable of producing a low-grade localized infection of the conjunctiva and is unable to invade other tissue. According to MacCallan, all races of human beings are equally susceptible to infection, but it is quite possible that certain individuals may possess a greater degree of resistance to infection than others, for example, we have noticed

TABLE 29

Summary of Filtration Experiments

reported (Harrison and Julianelle, 1937, Julianelle, Harrison, and Morris, 1937). Santoni (1940) grew human corneal cells, but could not demonstrate invasion by the virus.

Various workers have attempted to adapt the virus to the chorioallantois or yolk sac, but no definitely positive results have been obtained (Wright, 1937; Vancea, 1940, Burnet, Cuénod and Nataf, 1941, Julianelle, 1943).

Animal Inoculation Experiments

Before reviewing the reports of various workers on this subject the reader is reminded that in every experiment in which unfiltered human conjunctival material has been directly inoculated in the conjunctivae of apes or monkeys, the results are open to certain obvious criticisms This is so because neither normal human conjunctival secretion nor that of lower animals is free from bacteria, and pathological effects due to the presence of bacteria must be taken into consideration when assessing the significance of experimental results. Thus, for example, in the case of a monkey which has been injected with human conjunctival material, it is difficult to tell with certainty whether or not the lesions produced in the latter have been caused by the virus of trachoma or by a secondary invading bacterium The possibility of spontaneous conjunctivitis being developed by the animal resulting from traumatization of the mucous membrane is another chance that must be remembered (see Lumbroso, [illegible]) So far, no worker has [illegible]
in monkeys, apes, or ot [illegible]
those of human trachor [illegible]
doubt, however, that [illegible]
it has been appreciated by many investigators that all such experiments should be carefully controlled and that the utmost caution is required when interpreting the results The necessity for the adoption of such a critical attitude will be appreciated when it is recalled to memory that many of the experienced ophthalmologists who saw monkeys which had been inoculated with cultures of *B. granulosis* by Noguchi were deceived into believing that the animals were suffering from trachoma (see Robbins, 1935)

The susceptibility of apes and monkeys to trachoma.

In the experimental animal, trachoma is a mild affection which is not followed by cicatricial changes or pannus.

Hess and Romer (1906) were the first investigators to reproduce a disease resembling trachoma in the baboon by experimental inoculation with human material, this taking the form of a conjunctivitis which healed completely without scar formation Bajardi (1907) produced slight lesions in the macacus and cercopithecus monkeys, Bertarelli and Cecchetto (1908) were able to infect a variety of lower ape of the species *Inuus cynomolgus* after an incubation period of 17 days, Lindner likewise obtained a positive result using a lower ape, Kuht and Thielmann (according to Halberstaedter, 1912) were successful with Java apes, and Weiss (1933 *c*) employed the New World monkey *Cebus capucinus* Halberstaedter and Prowazek (1907 *a*, 1909) were able to infect the orang-utan, and transmit the [illegible]

[illegible] Thygeson and Proctor (1935) transmitted trachoma to 5 African sphinx baboons (*Mandrillus sphinx*) by inoculating them with bacteria-free filtrates prepared from human material (see also Lumbroso and Thygeson, 1933)

The *Macacus rhesus* monkey has been employed by Julianelle and Harrison (1933), but McCartney and Mayou (1930) and Stewart (1934) found that these

TABLE 30

EFFECT OF TEMPERATURE ON TRACHOMA VIRUS

Treatment of Material	*Fluid Used for Suspending Tissue*	*Effect on Virus*	*Authority*
15 minutes at 37° C	Normal serum	Nil	Julianelle and Harrison (1938)
90 minutes at 37° C.	Saline	Nil	Mijaschita (1908)
3 to 4 hours "at room temperature"	Tyrode of pH 7 4	Nil	Stewart (1933)
3 to 4 hours "at room temperature"	Broth of pH 7 4 to 7 8	Nil	Stewart (1933)
3 to 4 hours at 20° C	Patient's blood	*Nil*	*Julianelle and Harrison (1938)*
6 to 48 hours at 5–6° C	Dog plasma	Nil	Baroni and Michail (1932)

24 hours at 37° C.	Dog plasma	Nil	Baroni and Michail (1932)
24 hours at 35–37° C	Normal human serum Tyrode of pH 7 4	Nil	Stewart (1933)
3 days "at room temperature"	None	Nil	Baroni and Michail (1932)
7 days at 40° C.	Veal infusion broth of pH 7 6	Nil	Julianelle and Harrison (1938)
2 minutes at 120° F	Saline	Killed	Wright (1937)
15 minutes at 45–50° C	Veal infusion broth	Killed	Julianelle and Harrison (1938)
30 minutes at 50° C	Saline	Killed	Nicolle, Cuénod, and Blaizot (1913)
30 minutes at 58–63° C	Saline	Killed	Hess and Römer (1906)
45 minutes at 0° C or 10° C	Saline	Killed	Botteri (1912)
90 minutes at 35° C	Distilled water or Tyrode of pH 6 4	Killed	Stewart (1933)
3 hours at 43° C.	Saline	Killed	Botteri (1912)
4 hours at 15° C	Saline	Killed	Botteri (1912)
12 to 48 hours (tested *in vivo*)	In anterior chamber of rabbit's eye	Killed	Baroni and Michail (1932)
24 hours at 37° C	Tyrode, saline, or veal infusion broth of pH 7 6	Killed	Julianelle and Harrison (1938)
24 hours at 0° C	50 per cent glycerol	Killed	Stewart (1933)
2 to 3 days at 0° C	Broth or saline	Killed	Julianelle, Harrison, and Morris (1937)
6 to 10 days at 37° C	Dog plasma	Killed	Baroni and Michail (1932)
10 days at 37° C	Saline	Killed	Mijaschita (1908)

Centrifugalization

Low speed centrifugation for a short period of time had no effect in depriving the supernatant fluid of its infectivity (e g 1,500 r p m. for 5 minutes), but 30 minutes at 5,000 r p m was sufficient to render the supernatant fluid noninfective for monkeys (Julianelle and Harrison, 1938). The agent appears to be intimately linked with the tissues of the conjunctiva, and the washing of fragments by repeated centrifugalization and successive changes in saline fails to deprive them of their infectivity, according to Stewart (1933).

The Action of Certain Organic and Inorganic Compounds on the Virus

Trachoma virus is destroyed in 15 minutes at 37° C by the addition of a 25 to 35 per cent. solution of bile It is also inactivated after 3 to 4 hours by each of the following strengths of fluids 1 in 100,000 gentian violet, 1 in 1,000 tartar emetic, 2 per cent silver nitrate, 0 25 per cent phenol, and 4 per cent. cocaine (Julianelle and Harrison, 1938)

Cultivation

Attempts have been made to cultivate the virus, using the standard methods of Maitland and Maitland (1928), Li and Rivers (1930), Woodruff and Goodpasture (1931), and Burnet and Galloway (1934) No definite growth has been

been negative, according to Weiss (1933 c) Krümmel (1937) claims to have transmitted the infection from the human being to the conjunctiva of the rabbit.

Guinea-pigs The earlier experiments performed on these animals were uniformly negative Recently, von Szily (1935) reports that 2 to 3 months after intracerebral inoculation of guinea-pigs with trachomatous tissue, small nodules about the size of a millet seed appeared in the meninges Histological examination of these lesions failed to disclose any evidence of cellular reaction, and no perivascular infiltration or cuffing could be seen. The follicles in the meninges were comparatively large in size and occurred in the dura mater as well as in the pia and between the two membranes. They were distributed over a wide area and appeared to lie at some distance away from the blood vessels. The intra-ocular route of inoculation was also employed

Mice Attempts to infect these animals have failed, and Weiss (1933 c) reported that efforts to adapt the virus to mice by repeated intracerebral inoculation and passage were unsuccessful.

Goats and *dogs* have been inoculated, but without success, although in the past Schiele (1910) claimed to have obtained one positive result in a dog (see also Greeff, Frosch, and Clausen, 1908).

IMMUNITY IN TRACHOMA

Since trachoma is liable to recur in patients who have previously suffered from the condition, Julianelle and Harrison (1938) have studied the question of immunity to the disease in experimentally infected monkeys, and found that animals which had recovered from one attack of trachoma were susceptible to a second It was also found that the sera of human convalescents or normal persons failed to neutralize the virus when tested by inoculation of monkeys For these experiments conjunctival scrapings were suspended in broth, mixed with serum, whole blood, or plasma, kept at room temperature for 3 to 4 hours or 12 hours, or sometimes at 37° C for one hour only, and the mixture inoculated in monkeys No neutralization was, however, demonstrable by any of these procedures, and the absence of antibodies to the virus questions the value of serum therapy in the treatment of human trachoma. Julianelle (1939) has confirmed the low antigenic potency of the virus in monkeys

The intradermal test (Tricoire, 1931).

The antigen used for injection was prepared as follows Trachomatous granulation tissue was scraped from the surface of the conjunctiva and to it was added 10 times its volume of physiological saline The material was thoroughly ground up with a pestle in a mortar, then stored at 37° C. for 2 weeks, at the end of this time enough tincture of iodine was added to yield a final concentration of 1 per cent The dose injected consisted of 0,25 c c introduced intradermally with a fine needle after the usual manner of performing a skin test A positive result was signified by the formation of a red papule which developed in 48 hours and remained visible for 2 days In a negative test no reaction occurred, as the fluid was absorbed without any visible change on the skin surface

Practical value of the test Sedan (1933) performed the test on 150 persons suffering from the florid variety of trachoma, and found that 61 3 per cent gave a positive response, 16 per cent a doubtful result, and 22 6 per cent a negative reaction Control experiments were also performed on nontrachomatous subjects, and in these individuals the reaction was negative in the majority of instan[illegible] in earlier paper, however, Sedan (1931) reported that cases of tuber[illegible] syphilis sometimes gave a positive Tricoire test. Belot (1931) also inves[illegible] practical utility of the reaction in a series of 511 cases under his care and at the conclusion that the test was unreliable In his series of 400 cases of

monkeys were relatively resistant to infection. Blanc, Pages, and Martin (1939) used *M. sylvanus*, and after passage were able to infect man.

The susceptibility of different species of ape and monkey to trachoma virus has been studied by Stewart (1934), who found that the species most susceptible to experimental infection were monkeys of the 2 genera *Papio* (baboons) and *Lasiopyga* (grivets). Barbary apes and the various species of macaque, on the other hand, gave unsatisfactory results. Stewart in his experiments has adopted the wise precaution of examining the conjunctivae of each animal for evidence of spontaneous folliculosis before inoculation. He also advocates that suitable animals should first be tested by injection with nontrachomatous material prior to experimental inoculation. According to Stewart, the signs of disease seen in a susceptible animal are as follows:

> "Between 20 to 30 days after inoculation, the conjunctiva of the fornix is found covered with follicles, small, clear, blister-like projections about 1 mm. in diameter. They extend down to the upper edge of the tarsus but not further. When the animal is at rest they are clear, white or colourless and resemble drops of dew, if the animal struggles, however, the small vessels in their core fill with blood and they then look like drops of red jelly. The surface of the conjunctiva may be congested or not. There is no discharge and the animal gives no signs of feeling the condition. In a few cases early symptoms occur such as congestion, oedema, or false membrane formation either on the second day or after an interval, about the 10th to the 18th day."

Stewart regards the result of an experimental inoculation as positive only when follicles appear about the 20th to 30th day and cover the whole conjunctiva of the upper fornix. Control inoculations with certain nontrachomatous materials such as bacteria, and irritants like kaolin, failed to produce follicles on the healthy conjunctiva.

Bland (1944 *a*) reported that the grivet was susceptible, but that inclusions could not be demonstrated, they could be found, however, in men inoculated with grivet material. Bland (1944 *a, b*) stressed that baboons, grivets, and vervets are all prone to develop spontaneous folliculosis, identical in appearance with the changes induced by trachoma.

Cervicitis has been produced in baboons (Braley, 1939).

The susceptibility of other animals.

Rabbits. According to Julianelle and Harrison (1937), rabbits can be infected with the virus when inoculated intratesticularly. These workers obtained scrapings of conjunctival tissue from human cases, emulsified them in veal infusion broth, and then injected 0.5 c.c. of the fluid into each testicle of 2 rabbits. The first rabbit was killed after 1 week, the testicles were removed, emulsified in saline, and the material inoculated into the conjunctival surface of a rhesus monkey. A week later the animal developed follicles on its eyelid which persisted for 1 to 2 months. The testicle of the second rabbit was excised 2 weeks after inoculation, and the material was likewise introduced into another monkey. The result in the second animal suggested that the virulence of the virus had increased, since the monkey showed trachomatous lesions after a shorter incubation period of 5 to 7 days, and these did not heal for several months. By intratesticular passage in rabbits, Julianelle and Harrison (1937) thus claim to have isolated the virus of trachoma by freeing it from extraneous bacteria. No inclusion bodies were, however, found in the conjunctivae of infected monkeys (see also Julianelle, Harrison, and Morris, 1937).

Positive results have also been reported from Brazil by Busacca (1937 *a*) who inoculated material into the vitreous of rabbits and produced lymphocytic deposits in various organs. Micro-organisms resembling *Rickettsiae* were also found in the tunica vaginalis of the rabbit, in preparations stained with Victoria blue.

Efforts to adapt the virus to rabbits by repeated intracerebral inoculation have

been negative, according to Weiss (1933 *c*). Krümmel (1937) claims to have transmitted the infection from the human being to the conjunctiva of the rabbit.

Guinea-pigs. The earlier experiments performed on these animals were uniformly negative. Recently, von Szily (1935) reports that 2 to 3 months after intracerebral inoculation of guinea-pigs with trachomatous tissue, small nodules about the size of a millet seed appeared in the meninges. Histological examination of these lesions failed to disclose any evidence of cellular reaction, and no perivascular infiltration or cuffing could be seen. The follicles in the meninges were comparatively large in size and occurred in the dura mater as well as in the pia and between the two membranes. They were distributed over a wide area and appeared to lie at some distance away from the blood vessels. The intra-ocular route of inoculation was also employed.

Mice. Attempts to infect these animals have failed, and Weiss (1933 *c*) reported that efforts to adapt the virus to mice by repeated intracerebral inoculation and passage were unsuccessful.

Goats and *dogs* have been inoculated, but without success, although in the past Schiele (1910) claimed to have obtained one positive result in a dog (see also Greeff, Frosch, and Clausen, 1908).

IMMUNITY IN TRACHOMA

Since trachoma is liable to recur in patients who have previously suffered from the condition, Julianelle and Harrison (1938) have studied the question of immunity to the disease in experimentally infected monkeys, and found that animals which had recovered from one attack of trachoma were suspectible to a second It was also found that the sera of human convalescents or normal persons failed to neutralize the virus when tested by inoculation of monkeys. For these experiments conjunctival scrapings were suspended in broth, mixed with serum, whole blood, or plasma, kept at room temperature for 3 to 4 hours or 12 hours, or sometimes at 37° C. for one hour only, and the mixture inoculated in monkeys No neutralization was, however, demonstrable by any of these procedures, and the absence of antibodies to the virus questions the value of serum therapy in the treatment of human trachoma. Julianelle (1939) has confirmed the low antigenic potency of the virus in monkeys

The intradermal test (Tricoire, 1931).

The antigen used for injection was prepared as follows Trachomatous granulation tissue was scraped from the surface of the conjunctiva and to it was added 10 times its volume of physiological saline The material was thoroughly ground up with a pestle in a mortar, then stored at 37° C for 2 weeks; at the end of this time enough tincture of iodine was added to yield a final concentration of 1 per cent. The dose injected consisted of 0.25 c c. introduced intradermally with a fine needle after the usual manner of performing a skin test. A positive result was signified by the formation of a red papule which developed in 48 hours and remained visible for 2 days In a negative test no reaction occurred, as the fluid was absorbed without any visible change on the skin surface.

Practical value of the test Sedan (1933) performed the test on 150 persons suffering from the florid variety of trachoma, and found that 61 3 per cent gave a positive response, 16 per cent. a doubtful result, and 22 6 per cent. a negative reaction Control experiments were also performed on nontrachomatous subjects, and in these individuals the reaction was negative in the majority of instances. In an earlier paper, however, Sedan (1931) reported that cases of tuberculosis and syphilis sometimes gave a positive Tricoire test. Belot (1931) also investigated the practical utility of the reaction in a series of 511 cases under his care and arrived at the conclusion that the test was unreliable. In his series of 400 cases of typical

trachoma, only 50 per cent of them gave a positive reaction, while among 111 non-trachomatous control subjects, 43 per cent. gave a positive result.

The results of the Tricoire test, therefore, appear to be disappointing.

CHEMOTHERAPY IN TRACHOMA

A number of workers has reported favorably on the use of sulfonamides, given orally, parenterally, or locally (Sie Boen Lian, 1938, Burnet, Cuénod, and Nataf, 1939; MacCallan, 1939, *Rev. internat du Trachome*, 1939, *16*, 137, Giller, 1940; Lee and Rottenstein, 1940, Miterstein and Stern, 1945; Sorsby, 1945; Thygeson. 1945). Some claims have also been made for penicillin (Darius, 1945, Thygeson, 1945).

In vitro, sulfonamide has no appreciable effect on the infectivity of virus (Julianelle and Smith, 1942). It is difficult to say whether the effect of chemotherapeutic agents is chiefly on the virus or on secondary invaders.

RELATIONSHIP OF TRACHOMA TO OTHER VIRUSES

It appears that the viruses of trachoma and inclusion conjunctivitis are closely related, and this subject is discussed on p 720.

The studies of Rake, Shaffer, and Thygeson (1942) suggest that antigenic components are shared between the virus of trachoma and the members of the LGI-psittacosis-pneumonitis group (see p. 720).

RELATIONSHIP OF TRACHOMA VIRUS TO *RICKETTSIAE*

There is no doubt that some of the morphological forms of trachoma virus present a superficial resemblance to *Rickettsiae*, and Busacca (1935) has, in fact, proposed the term *Rickettsia trachome*. Certain workers have advanced the view that trachoma virus is really rickettsial in nature (Busacca, 1937 *b*, Cuénod and Nataf, 1937 *c*, Poleff, 1937, 1938, Foley and Parrot, 1938). Venable and Pollock (1943) have published a general review of the question of the relationship of trachoma to *Rickettsiae*.

A number of other workers, with whom we agree, do not accept that the trachoma inclusions are strictly identical with *Rickettsiae* (Thygeson, 1938 *b*, Baltazard, personal communication, Gonnert and Wohlrab, 1942)

As further support for the relationship between trachoma virus and *Rickettsiae*, Poleff (1936 *a, b*) claimed to have obtained an abundant growth of rickettsia-like organisms in tissue culture (see also 1939)

Then, positive Weil-Felix reactions have been demonstrated in the sera of trachoma cases (Poleff and Nain, 1938, Postić, 1939, Gomes and Jordão, 1940) Poleff and Nain have also demonstrated skin reactions to heated *Proteus* OX19 antigen It seems to be generally agreed, however, that the results of Weil-Felix tests are so variable and inconclusive as to be of no value from the diagnostic point of view, there is no evidence from this test that the causal agent of trachoma is rickettsial in origin (Kirk, McKelvie, and Drysdale, 1939, Manditch, 1939, Reis, 1939, Goreczky and von Grósz, 1941).

Additional evidence concerns the alleged transmission of trachoma by lice Cuénod and Nataf (1936, 1937 *a*) claimed that the virus multiplied rapidly in the louse without losing its pathogenicity for man or ape They have suggested (1937 *d*) that the disease is spread by rubbing the eyelids with fingers contaminated with crushed lice (see also Foley and Parrot, 1937 *b*) However, Trapesontzewa (1939) and Weigl (1939) failed to demonstrate *Rickettsiae* in lice.

It does not appear, therefore, that there is much justification for regarding the trachoma virus as a *Rickettsia*

BIOLOGICAL THERAPY IN TRACHOMA

Autohemotherapy has been tried by Fehmi (1931) and found to give but little relief, but Lerner (1937) practiced the same method and after injecting 10 c c. of

blood every other day until 15 doses were administered, reported improvement in early cases

A substance known as "trachocid," devised by Brecher (1935), consisting of bee venom and snake venom which were rendered atoxic and nonirritant by a chemical process, has been recommended by Lobel (1936) Attempts to immunize patients against the disease have been made by Derkač (1937), who excised fragments of tissue from the conjunctivae of children and then transplanted the material into the subcutaneous surface of the forearm Derkač states that this procedure modified the course of the disease which subsided in a few months, and, furthermore, that individuals so treated acquired immunity to reinfection.

Esteban (1933) reports good results with local immunotherapy, and has used a vaccine prepared after the method originally employed by Pietro Vancea, consisting of a saline emulsion of trachomatous granulation tissue which had been heated to 60° C. for 30 minutes Galeazzi (1934) and Ruata (1934) have used a bacterial vaccine consisting of organisms isolated from the conjunctival sac, Krylov and Rostovtsev *(1936) reported poor results when using brilliant green,* which was not as effective as copper sulfate.

Inclusion Urethritis of the Male

Inclusion bodies and elementary bodies resembling those found in inclusion blennorrhea have also been detected in the male urethra Lindner (1909) reported their presence in cases of urethritis studied by him, in which gonococci were absent (see also Fritsch, Hofstaetter, and Lindner, 1910, and Heymann, 1913). Thygeson and Mengert (1936) also found inclusion bodies in a man who developed subacute urethritis 7 days after sexual intercourse, which later subsided and gave rise to a chronic intermittent discharge which lasted 7 months before it healed completely. In this case inclusions were found in urethral smears made 3 months after the onset of symptoms

Harrison and Worms (1939) discuss the rôle of the virus in the causation of cases of "nonspecific urethritis" (see also Meenan, 1947).

INFECTION OF THE RESPIRATORY TRACT

Infections of the upper respiratory passages due to this virus have been reported by Morax (1933), Aust (1933), and Poelchau (1937). The accurate diagnosis of such cases is, however, a difficult problem, as inclusion bodies cannot easily be found (Thygeson and Mengert, 1936) Moreover, if they are found a certain amount of care is necessary in the interpretation of the result, owing to the fact that Broadhurst *et al* (1936) have demonstrated inclusion bodies in films of saliva obtained from the mouth, throat, and other parts of the respiratory tract of normal persons

ACCIDENTAL INFECTIONS

Infection has occurred in doctors and nurses accidentally infected with secretions or blood during gynecological operations or eye examinations (Thygeson and Mengert, 1936, Julianelle, 1937).

MORBID HISTOLOGY

The histopathological lesions of blennorrhea neonatorum have been studied by Wolfrum (1910), who came to the conclusion that the absence of follicles in chil-

trachomatous follicles by their small size and the absence of a circumscribed band of fibrous tissue surrounding them Healed lesions of inclusion conjunctivitis, moreover, show no cicatricial tissue formation, whereas this invariably occurs as the end result of trachoma Thygeson and Mengert (1936) studied biopsy tissue excised from the lower fornix in a case of inclusion conjunctivitis, 6 weeks after its onset. In sections they found that the epithelium was of normal thickness, but was heavily infiltrated with polymorphonuclear leukocytes, together with diffuse subepithelial infiltration with plasma cells and numerous lymphocytes. There were also present numerous characteristic follicles with avascular centers, composed of large mononuclear cells surrounded by plasma cells and lymphocytes

EPIDEMIOLOGY

The infection, in its various clinical forms, has a wide distribution in Germany, Austria, France, various other parts of Europe, Russia, Japan, Australasia, and N. America (Heymann, 1909, Lindner, 1909, 1910, 1911, Noguchi and Cohen, 1911, Huntemueller and Paderstein, 1913, Axenfeld, 1914, Brown, 1914, Williams, 1914;

CHAPTER LXVI

INFECTION WITH THE VIRUS OF INCLUSION CONJUNCTIVITIS

This virus most commonly causes infection of the conjunctiva in newborn babies (virus ophthalmia neonatorum), it also causes conjunctivitis in older persons, and this is frequently contracted in swimming pools It is also responsible for a mild form of cervicitis and urethritis. The distinguishing feature of the infection is the presence of basophilic intracytoplasmic inclusions in epithelial cells, identical with those described in trachoma (Halberstaedter and Prowazek, 1909, 1910, Heymann, *1909, Stargardt, 1909; Herzog, 1910).*

CLINICAL FEATURES OF CONJUNCTIVITIS

The incubation period in the newborn infant is 5–9 days, in the adult the incubation is usually about 7 days (Thygeson, 1934).

The clinical features, which are not particularly distinctive, are as follows (see, e g, Noguchi and Cohen, 1911; *Gradle, 1916;* Lumbroso, 1933; McKee, 1935, *Thygeson and Mengert, 1936, Julianelle, 1937).*

There is edema of the conjunctivae, with mucopurulent exudate. The conjunctivae become granular, due to the formation of translucent follicles. The preauricular glands may be swollen and tender. The illness usually lasts for 3–6 months Cicatrization is most unusual, thus distinguishing the condition from trachoma, which is otherwise closely similar.

INVOLVEMENT OF THE GENITO-URINARY TRACT

Inclusion Cervicitis of the Female

The evidence shows that in the case of newborn children who develop the disease, the infection is acquired at birth from the infected genital passages of the mother.

Thus, Halberstaedter and Prowazek (1909, 1910) and Heymann (*1910*) found inclusions in epithelial cells derived from the genital tract of mothers whose children *had developed the disease shortly after birth.*

Thygeson and Mengert (1936) likewise obtained similar results and, in a series of excellent microscopic preparations, they clearly demonstrated the presence of numerous elementary bodies in scrapings obtained from the cervix uteri of infected mothers Vaginal smears, on the other hand, yielded less satisfactory results, for although the virus could be found in the material examined, the detection of cell inclusions proved to be an exceedingly difficult task, owing to the density of the cellular and bacterial content of the vaginal exudate These workers, therefore, concluded from their studies that the cells with inclusions found in vaginal secretion were merely desquamated cells that had been shed from the epithelial covering of the cervix uteri which was the active focus of infection Hamburger (*1934*), on the contrary, concluded that the virus multiplied in the vagina and not in the cervix. He also expressed the opinion that inclusion vulvitis should be recognized as a clinical entity.

The epithelial cells involved are the transitional cells just within the external os (Thygeson and Stone, *1942 a)*

It should be realized that inclusions may be only scanty in the cervical scrapings of mothers of babies with virus ophthalmia, and may not be found in more than a small percentage of cases where infection is present (Sorsby, Hoffa, and Young. 1944)

by Thygeson and Mengert (1936), neither have they been able to detect the existence of a stainable matrix. Thygeson and Mengert observe, however, that the inclusion cavity "is probably filled with a fluid which has slight agglutinating properties," so that inclusion bodies which have been extruded from cells consist of clumps of elementary bodies, which remain as compact masses. It was also noted by the same 2 observers that the virus readily entered the epithelial cells of the conjunctiva, cervix, or urethra, but never attacked the keratinized transitional epithelial cells of the adult vagina or that found at the margin of the eyelids

Life Cycle of the Virus

This has been carefully studied by Thygeson (1934), who did so by artificially transferring infection from the affected eye to the normal eye of a patient, after which he obtained scrapings from the lower tarsal conjunctiva at regular intervals, and in this manner was able to study the developmental phases of the virus

Stained films made from scrapings obtained before inoculation showed no inclusion bodies, while after infection he observed the following changes

"30 hours Conjunctiva normal Scrapings revealed numerous inclusions, 99 per cent. being of the elementary-body type, the remaining 1 per cent being of mixed type There were no leucocytes

"51 hours Conjunctiva normal Numerous inclusions, 99 per cent being of early initial-body type A few free elementary bodies and an occasional polymorphonuclear neutrophile

"75 hours Conjunctiva normal. Numerous inclusions, mostly of mixed type, with an occasional elementary-body type

"100 hours Conjunctiva normal Numerous inclusions, mainly of elementary-body type. A few very early initial-body inclusions Increased leucocytic reaction

"122 hours Inflammation and secretion were beginning Inclusions of initial to mixed type predominated Many polymorphonuclear leucocytes

"144 hours Inflammation and secretion marked Mixed inclusions predominated A few elementary-body inclusions The cycle had now become somewhat indistinct.

"165 hours Majority of inclusions of elementary-body type with a few of the initial-body type."

From the above results it was concluded that the complete cycle of development from the elementary body stage back to the same stage was observed during the first 6 days of incubation It thus appears that the life cycle of the inclusion blennorrhea virus is approximately 48 hours, which is of particular interest since it coincides with the duration of the life cycle of psittacosis virus (Bedson, 1933).

Attempts to Cultivate the Virus

Noguchi and Cohen (1913, 1914) claimed to have been able to cultivate the inclusion bodies found in this disease, but the work has lacked confirmation. Efforts to grow the virus on the chorio-allantoic membrane of the developing chicken embryo have been unsuccessful (Thygeson and Mengert, 1936).

Transmission to Man

Man can be infected by inoculating the conjunctival sac (Thygeson, 1934; Allen, 1944).

Inoculation of Animals

Lindner (1909) injected secretion from a human case of inclusion conjunctivitis into the eyelid of a *Macacus rhesus* monkey, and reproduced a granulomatous condition

Later, Fritsch, Hofstaetter, and Lindner (1910) similarly infected monkeys with conjunctival secretion obtained from infected infants, as well as the vaginal secretion derived from the mothers of these children. They also obtained positive re-

Comberg, 1920; Chaillous and Nida, 1922, Kalt, 1922; Morax, 1922, 1933; Engelking, 1925, Paderstein, 1925; Rohrschneider, 1926; Sandmann, 1926; Bahn, 1927; Fodor, 1929, Rötth, 1932, Thygeson, 1934; Kankrov, 1935; Rameer, 1935; Rutherford, 1935; Fujita and Nagashige, 1936, Thygeson and Mengert, 1936; Howard, 1938, Julianelle, Harrison, and Lange, 1938; Thygeson and Stone, 1942 a, Derrick, 1943; Williams, 1946).

In Britain, cases of ophthalmia neonatorum have been described (Sorsby, Hoffa, and Young, 1944), but investigations that we made in London did not suggest that inclusion cervicitis or urethritis was anything but exceedingly rare in patients attending V. D. clinics.

A reservoir of infection is afforded by mild cases of inclusion cervicitis and urethritis, these infections being transmitted venereally between adults. Babies born to mothers harboring the virus in the cervix may develop virus ophthalmia. Swimming-pool conjunctivitis is contracted by fouling of the water with urine. Infection may also be transmitted mechanically, as by infected eye instruments, or accidentally, as in doctors or nurses.

PROPERTIES OF THE VIRUS

Filtrability and Size of the Virus

Botteri (1912) and Gebb (1914) proved that the infective agent of the disease was capable of traversing the pores of earthenware filters. The virus is filtrable through Elford's collodion filters of APD 0.65 μ (Thygeson, 1934; Julianelle, Harrison, and Lange, 1938, Julianelle, 1940). Stained EB's measure 0.25 μ, and initial bodies 0.3–0.8 μ (Thygeson, 1934; Tilden and Gifford, 1936).

Morphology and Staining Reactions

Films prepared from conjunctival secretion or scrapings should be made on clean glass slides and stained with dilute Giemsa's stain, according to any one of the methods described in Ch. III. Rivers's modification of Castaneda's method has been recommended by Thygeson and Mengert (1936). The elementary bodies of inclusion conjunctivitis virus stain poorly with aniline dyes and are gram negative in reaction [illegible]
(Fodor, 1935 [illegible]
no different [illegible]
[For a good illustration of these bodies see Heymann (1913).]

The inclusion bodies of inclusion conjunctivitis are now regarded by Thygeson and other workers as intracellular colonies of the virus.

Appearance of the Virus when Seen by Darkfield Illumination

The elementary and initial bodies appear as highly refractile dots of light when viewed by this method. They are comparatively uniform in shape and size and present a characteristic appearance when examined by oblique light. Even though the bodies present a striking picture by this method, we advise that all films should first be stained and examined by direct light, and then, only if elementary bodies are thought to be present, should their existence be confirmed by darkground examination (see van Rooyen, 1937).

Multiplication and Development of the Virus in Tissues

The successive stages exhibited by the inclusion conjunctivitis virus during its growth in conjunctival epithelial cells are similar to those described by Lindner (1910). Thus, the virus colony develops at the expense of the cell cytoplasm, and in so doing forms a vacuole which is first filled by initial bodies and later by elementary bodies, which begin by appearing from the center of the mass.

The bridge or dumb-bell forms described by Lindner have not been observed

by Thygeson and Mengert (1936), neither have they been able to detect the existence of a stainable matrix. Thygeson and Mengert observe, however, that the inclusion cavity "is probably filled with a fluid which has slight agglutinating properties," so that inclusion bodies which have been extruded from cells consist of clumps of elementary bodies, which remain as compact masses It was also noted by the same 2 observers that the virus readily entered the epithelial cells of the conjunctiva, cervix, or urethra, but never attacked the keratinized transitional epithelial cells of the adult vagina or that found at the margin of the eyelids

Life Cycle of the Virus

This has been carefully studied by Thygeson (1934), who did so by artificially *transferring infection from the affected eye to the normal eye of a patient, after* which he obtained scrapings from the lower tarsal conjunctiva at regular intervals, and in this manner was able to study the developmental phases of the virus

Stained films made from scrapings obtained before inoculation showed no inclusion bodies, while after infection he observed the following changes:

"30 hours Conjunctiva normal Scrapings revealed numerous inclusions, 99 per cent. being of the elementary-body type, the remaining 1 per cent. being of mixed type. There were no leucocytes.

"51 hours Conjunctiva normal Numerous inclusions, 99 per cent being of early initial-body type. A few free elementary bodies and an occasional polymorphonuclear neutrophile

"75 hours Conjunctiva normal Numerous inclusions, mostly of mixed type, with an occasional elementary-body type.

"*100 hours Conjunctiva normal Numerous inclusions, mainly of elementary-body type* A few very early initial-body inclusions Increased leucocytic reaction

"122 hours Inflammation and secretion were beginning Inclusions of initial to mixed type predominated Many polymorphonuclear leucocytes

"144 hours Inflammation and secretion marked Mixed inclusions predominated A few elementary-body inclusions The cycle had now become somewhat indistinct.

"165 hours Majority of inclusions of elementary-body type with a few of the initial-body type"

From the above results it was concluded that the complete cycle of development [illegible] observed during the [illegible] the inclusion blen- [illegible] interest since it co- [illegible] Bedson, 1933).

Lindner (1909) injected secretion from a human case of inclusion conjunctivitis into the eyelid of a *Macacus rhesus* monkey, and reproduced a granulomatous condition

Later, Fritsch, Hofstaetter, and Lindner (1910) similarly infected monkeys with conjunctival secretion obtained from infected infants, as well as the vaginal secretion derived from the mothers of these children *They also obtained* positive re-

Comberg, 1920, Chaillous and Nida, 1922; Kalt, 1922, Morax, 1922, 1933, Engelking, 1925, Paderstein, 1925; Rohrschneider, 1926; Sandmann, 1926, Bahn, 1927, Fodor, 1929, Rotth, 1932; Thygeson, 1934; Kankrov, 1935, Rameer, 1935, Rutherford, 1935; Fujita and Nagashige, 1936; Thygeson and Mengert, 1936; Howard, 1938, Julianelle, Harrison, and Lange, 1938; Thygeson and Stone, 1942 *a*, Derrick, 1943, Williams, 1946).

In Britain, cases of ophthalmia neonatorum have been described (Sorsby, Hoffa, and Young, 1944), but investigations that we made in London did not suggest that inclusion cervicitis or urethritis was anything but exceedingly rare in patients attending V. D. clinics

A reservoir of infection is afforded by mild cases of inclusion cervicitis and urethritis, these infections being transmitted venereally between adults. Babies born to mothers harboring the virus in the cervix may develop virus ophthalmia. Swimming-pool conjunctivitis is contracted by fouling of the water with urine. Infection may also be transmitted mechanically, as by infected eye instruments, or accidentally, as in doctors or nurses.

PROPERTIES OF THE VIRUS

Filtrability and Size of the Virus

Botteri (1912) and Gebb (1914) proved that the infective agent of the disease was capable of traversing the pores of earthenware filters. The virus is filtrable through Elford's collodion filters of APD 0 65 μ (Thygeson, 1934, Julianelle, Harrison, and Lange, 1938; Julianelle, 1940). Stained EB's measure 0.25 μ, and initial bodies 0 3–0.8 μ (Thygeson, 1934; Tilden and Gifford, 1936).

Morphology and Staining Reactions

Films prepared from conjunctival secretion or scrapings should be made on clean glass slides and stained with dilute Giemsa's stain, according to any one of the methods described in Ch. III. Rivers's modification of Castaneda's method has been recommended by Thygeson and Mengert (1936). The elementary bodies of inclusion conjunctivitis virus stain poorly with aniline dyes and are gram negative in reaction The inclusions can also be demonstrated by supravital staining methods (Fodor, 1935) Morphologically, the inclusion bodies present in this condition are no different from the Halberstaedter-Prowazek inclusion bodies found in trachoma. [For a good illustration of these bodies see Heymann (1913).]

The inclusion bodies of inclusion conjunctivitis are now regarded by Thygeson and other workers as intracellular colonies of the virus.

Appearance of the Virus when Seen by Darkfield Illumination

The elementary and initial bodies appear as highly refractile dots of light when viewed by this method. They are comparatively uniform in shape and size and present a characteristic appearance when examined by oblique light Even though the bodies present a striking picture by this method, we advise that all films should first be stained and examined by direct light, and then, only if elementary bodies are thought to be present, should their existence be confirmed by darkground examination (see van Rooyen, 1937)

Multiplication and Development of the Virus in Tissues

The successive stages exhibited by the inclusion conjunctivitis virus during its growth in conjunctival epithelial cells are similar to those described by Lindner (1910). Thus, the virus colony develops at the expense of the cell cytoplasm, and in so doing forms a vacuole which is first filled by initial bodies and later by elementary bodies, which begin by appearing from the center of the mass

The bridge or dumb-bell forms described by Lindner have not been observed

and animal pathogenicity It would appear, nevertheless that some antigenic components are shared by the two groups, as convalescent sera may fix complement with LGI-psittacosis antigens (Rake, Shaffer, and Thygeson, 1942).

sults with urethral secretion derived from male cases of inclusion urethritis, in which the presence of gonococci had been excluded by careful bacteriological examination These workers succeeded in transmitting the infection from one monkey to another, and demonstrated the presence of inclusion bodies and free elementary bodies in conjunctival scrapings prepared from the infected animals. Baboons were also found to be susceptible to infection.

Heymann (1910, 1913) reproduced conjunctivitis in baboons and cercopithecus monkeys, using conjunctival secretion obtained from infected children and also material from the genitalia of their parents Thygeson (1934) and Thygeson and Mengert (1936) likewise reproduced inclusion conjunctivitis in monkeys, and found that the sphinx baboon was more susceptible to infection than the *Macacus rhesus* monkey. They were also able to produce cervicitis in female baboons, 8 to 12 days after the intrauterine inoculation of infected vaginal secretion from human cases Julianelle (1940), and Julianelle, Harrison, and Lange (1938), confirm the susceptibility of rhesus monkeys to conjunctival inoculation.

The rabbit, guinea-pig, white rat, pig, and *dog* are resistant to experimental infection (Thygeson, 1934).

IMMUNITY

There appears to be no general immunity following infection with inclusion conjunctivitis virus Noguchi and Cohen (1911) have recorded the occurrence of relapses or reinfections, and a number of workers have drawn attention to the fact that mothers who carry the virus are liable to infect their own eyes with the organism (James, 1930; Aust, 1933, and Thygeson, 1934). There would appear to be no neutralizing antibodies in the sera of individuals who have recovered from one attack of inclusion conjunctivitis. Thygeson and Mengert (1936) clearly demonstrated that convalescent patients' sera failed to neutralize the virus *in vitro,* and that baboons inoculated with a mixture of the two developed the disease in due course Efforts to agglutinate the virus also failed, and these workers suggest that the localization of the virus in epithelial tissues may conceivably have been responsible for the absence of agglutinins in the patients' sera Thygeson's view is of interest to ourselves, since during the course of our own studies on the elementary bodies of molluscum contagiosum (van Rooyen, 1938) we too failed to detect the presence of agglutinins in the sera of patients, and attributed their absence to a similar cause

SPECIFIC TREATMENT

Oral or local sulfonamides are said to be effective in man or monkey, inclusions disappearing rapidly (Giddens and Howard, 1940, Thygeson, 1941, Thygeson and Stone, 1942 *b*) Local penicillin is also of value (Sorsby, 1945)

RELATIONSHIP TO TRACHOMA

Clinically, inclusion conjunctivitis is mild and ends in complete recovery, whereas trachoma leads to permanent cicatrization In the early stages the two conditions are, however, closely similar

The two agents are microscopically indistinguishable, and Lindner (1925, 1935 *a, b, c*) has regarded the viruses of trachoma and "paratrachoma" (inclusion conjunctivitis) as identical The viruses are evidently closely related, yet in infected monkeys no cross protection can be demonstrated, indicating differing antigenic structures (Julianelle, 1940).

RELATIONSHIP TO LGI-PSITTACOSIS

Morphologically the trachoma and inclusion conjunctivitis viruses resemble fairly closely members of the LGI-psittacosis group There are, however, many points of biological difference between the two, particularly as regards cultivation

CHAPTER LXVII

INTRODUCTION: THE PNEUMONITIS-PSITTACOSIS-LGI GROUP[1]

THE MEMBERS of this group have common biological properties that separate them somewhat from other viruses. In certain respects the members of this group may be considered as intermediate between *Rickettsiae* and viruses, although classifiable as viruses. Thus they are all relatively large, and are readily stained with simple basophilic dyes (so-called Castañeda positive). They form large basophilic inclusions in endothelial and epithelial cells, and grow well in the yolk sac. They infect a wide range of experimental animals, and some cause infection of birds. Certain viruses produce what appears to be an endotoxin, and some are sensitive to sulfonamides and antibiotics.

The best known agents in the group are. pneumonitis viruses, such as meningo-pneumonitis (MP), Baker's feline pneumonitis, pneumonia virus of mice (PVM), Nigg's mouse pneumonitis virus, SF, and Louisiana viruses (Ch LXVIII), psittacosis and ornithosis (Ch LXX and LXXI), lymphogranuloma inguinale (Ch LXXII). It is convenient also to discuss in this section the question of atypical pneumonia, the etiology of which is not yet clarified (Ch LXIX)

BIOLOGICAL PROPERTIES

In general, the effects produced in experimental animals and eggs are similar. However, there are definite differences between the Castañeda positive viruses,

TABLE 31

using sera prepared in roosters (St. John and Gordon, 1947). In this work, in addition to the better known viruses, study was made of Ann Arbor virus and Illinois virus Cross neutralization tests were performed with rooster antisera and virus suspensions, the test mixtures being inoculated in mice nasally or cerebrally according to the virus. The results, including those of Hilleman (1945) may be tabulated as follows:

TABLE 32

ANTIGENIC RELATIONSHIPS IN THE PNEUMONITIS PSITTACOSIS GROUP AS SHOWN BY VIRUS NEUTRALIZATION TESTS

Viruses	Antisera					
	Feline Pneumonitis	*Ann Arbor (Kempf)*	*Ann Arbor (St John)*	*Mouse Pneumonitis*	*LGI*	*MP*
Feline pneumonitis	+	o		o	o	o
Ann Arbor .	o	+	+	+	o	o
Mouse pneumonitis (Chicago)	o	±	±	+	o	o
Mouse pneumonitis (Atherton)				+		o
LGI	o		o	o	+	o
MP	o	+	o	o	o	+
Ornithosis .				o		+
Psittacosis . .	o			o	o	o
SF . .	o			o	o	o
Illinois .	o			o	o	o

+ = neutralization ± = partial o = no neutralization

These tests show that each virus studied, except Ann Arbor, possesses a distinctive antigen Ann Arbor seems to share a common antigen with mouse pneumonitis Meningopneumonitis and ornithosis antigens appear to be identical

CONCLUSIONS

We may conclude that the viruses named above are antigenically related, yet are mostly distinct entities Probably further work will show antigenic relationships between these pneumonitis.
It is eviden and antigenic relationships or es as follows (1) lymphogranuloma inguinale, (2) psittacosis, ornithosis, and meningopneumonitis; (3) SF, Louisiana, Baker's virus, Ann Arbor, and mouse pneumonitis

and by the choice of suitable animals and routes of inoculation it is often possible to be reasonably certain of the correct classification of an unknown basophilic virus Some of the differential tests that may be used are indicated in Table 31. In addition, use may be made of pigeons and other birds, complement fixation, cross immunity and cross neutralization tests, especially in mice (see below). Study of any toxin produced may also be of value.

ANTIGENIC RELATIONSHIPS

The question of the antigenic relationship between the members of the group has been investigated by various means, particularly by complement fixation, virus neutralization, and active immunity tests. Cross reactions are more commonly observed by the complement fixation reaction, and are less commonly demonstrated by virus neutralization or cross resistance tests.

Complement fixation tests with virus antigens and human or animal sera suggest that the following v

components psittacosis,

ana virus, SF, and mouse

Corey, 1942, Eaton, Martin, and Beck, 1942; Smadel, Wertman, and Reagan, 1943, Beck, Eaton, and O'Donnell, 1944; Florman, 1945, Larson and Olson, 1946).

The relation between certain of these viruses is closer than between others, and various observations may be quoted.

1. Psittacosis antisera will fix complement with ornithosis and LGI antigens (Levine, Holder, and Bullowa, 1943; Smadel, Wall, and Gregg, 1943; Larson and Olson, 1946) Psittacosis and ornithosis are closely related, but can be differentiated by active immunity tests in mice (Beck, Eaton, and O'Donnell, 1944).

2 The sera of LGI cases will fix complement with antigens prepared from the following viruses

Baker's virus . ..	... Hamre and Rake, 1944; Vilches, Parodi, and Chialvo, 1946
Ornithosis ..	. Smadel, Wertman, and Reagan, 1943, Bowser and Nigg, 1946
Psittacosis	Smadel, Wertman, and Reagan, 1943; Levine, Holder, and Bullowa, 1943, De Burgh, Jackson, and Williams, 1945, Bowser and Nigg, 1946
Louisiana . .	Larson and Olson, 1946
Meningopneumonitis ..	Eaton, Martin, and Beck, 1942

3 A rise in titer to both LGI and meningopneumonitis viruses has been recorded in the sera of cases of pneumonia due to SF and ornithosis viruses (Eaton, 1945). The sera of pigeons infected with ornithosis proved rather more specific, and fixed complement with meningopneumonitis, but not with LGI (Eddie and Francis, 1942) The close relationship between ornithosis and meningopneumonitis has been confirmed by CF tests by Larson and Olson (1946), and in virus neutralization tests in mice using fowl sera (Hilleman and Gordon, 1944, Hilleman, 1945, St. John and Gordon, 1947)

4. The SF virus is related to, but can be separated from, ornithosis, it is distinct from meningopneumonitis, psittacosis, and lymphogranuloma (Beck and Eaton, 1942, Beck, Eaton, and O'Donnell, 1944, Meiklejohn, Beck, and Eaton, 1944).

5. Sera to Louisiana virus were found to fix complement with psittacosis, ornithosis, and LGI viruses, but mice and guinea-pigs immunized by killed meningopneumonitis and psittacosis viruses were not resistant to Louisiana virus (Larson and Olson, 1946).

6 Baker's virus is related antigenically to psittacosis and mouse pneumonitis (Thomas and Kolb, 1943), but in virus neutralization tests with fowl sera is seen to occupy a distinctive position without showing cross reactions (Hilleman and Gordon, 1944, Hilleman, 1945)

7 More specific differentiation has been achieved by virus neutralization tests,

gray-lung rodent virus of Andrewes and Glover (1945), and an agent causing lesions in guinea-pigs (Lépine, Sautter, and Lamy, 1943; Lépine and Sautter, 1945).

PNEUMONITIS VIRUSES PROBABLY INFECTING MAN

Meningopneumonitis (MP) Virus

This virus was isolated from ferrets inoculated with throat washings from patients suffering from an influenza-like disease (Francis and Magill, 1938). It has been isolated from a fatal case of AP by Meiklejohn, Beck, and Eaton (1944).

1. The EBs are basophilic and measure 354 ± 41 mμ in electron micrographs (Kurotchkin *et al*, 1947).

2. It infects mice and ferrets nasally, and monkeys and mice cerebrally Rabbits can be infected tracheally (Morgan, 1946), cotton rats, hamsters, and guinea-pigs are also susceptible (see Table 31).

3. The virus grows in the yolk sac, and produces a toxin killing mice rapidly on intravenous injection. Antitoxic sera can be prepared, and are highly specific (Rake and Jones, 1944). It can also grow in the allantoic sac (Francis and Gordon, 1945).

4. The virus is sensitive *in vivo* to penicillin (Parker and Diefendorf, 1944)

5 As regards sulfonamides, Rake, Jones, and Nigg (1942) did not find any evidence of sensitivity of the virus in mice Rake and Hamre (1944) found that sulfamerazine had no effect on the endotoxin, or on the early deaths produced thereby in mice, however, it prevented later deaths, which are probably due to infection rather than toxemia.

6. Aerosolized virus is sensitive to triethylene glycol (Rosebury *et al.*, 1947).

7. The virus is related to psittacosis, ornithosis, and LGI viruses (see above).

Pneumonia Virus of Mice (PVM)

This virus was isolated by Horsfall and Hahn (1940) from the lungs of apparently healthy mice by passage Horsfall *et al* (1943) recovered 12 strains from patients with AP, all strains were antigenically related to PVM.

1 The virus forms basophilic EBs It measures 100–150 mμ by ultrafiltration (Horsfall and Hahn, 1940, but see also below)

2 The lungs of infected mice contain an agent that agglutinates mouse red cells The agglutination is inhibited by antiserum (Mills and Dochez, 1944). Maximum agglutinability develops after heating the lung extract at 75° C for 5 minutes, the agent is absorbed from active extracts by mouse red cells and fresh normal mouse

3 Curnen and Horsfall (1947), Curnen, Pickels, and Horsfall (1947) have shown that PVM can be separated into free and combined virus. Virus in the combined state, as found in lightly ground lung suspensions, is infectious but does not agglutinate red cells Heat treatment of combined virus releases virus which is noninfective but agglutinates red cells. Free virus is liberated from infected lungs by perfusing prior to removal and then mincing finely, such virus is infectious, and causes hemagglutination Heat treatment renders free virus noninfective, but this still causes agglutination Heat-released virus mixed with lightly ground lung suspension does not give agglutination (artificially combined PVM). The principal hydrated virus particles of naturally free or heat-released PVM were found to have

CHAPTER LXVIII

THE PNEUMONITIS GROUP

A considerable number of viruses have been isolated that have the property of causing pneumonia in man and animals, and are characterized by the formation of basophilic elementary and inclusion bodies.

PNEUMONITIS VIRUSES OF ANIMALS

Nigg's Mouse Pneumonitis Virus

This virus was isolated by Nigg (1942)[1] from apparently normal Swiss mice, and has the following properties

1 The virus forms basophilic EB's The EB's measure 497± 77mμ in electron micrographs (Kurotchkin *et al*, 1947).

2. It is sensitive to sulfonamides (Rake, Jones, and Nigg, 1942, Eaton and Hanford, 1945).

3 Antisera can be prepared in chickens, and cause flocculation of EB's (Hilleman and Gordon, 1943).

4 A toxin is produced when growing in the yolk sac, killing mice rapidly on intravenous injection, antitoxic sera are highly specific (Rake and Jones, 1944).

5 The virus is antigenically related to meningopneumonitis, LGI, and Baker's virus (Thomas and Kolb, 1943, Nigg and Eaton, 1944)

6 The virus is pathogenic for mice, cotton rats, and hamsters (see Table 31).

Baker's Feline Pneumonitis Virus

This virus was isolated by Baker (1942) from a respiratory distemper-like disease of cats

1 It forms basophilic EB's and can be transmitted to mice (see Table 31), rabbits, guinea-pigs, hamsters, and eggs (Baker, 1944). The EB's have been found to measure 466± 78mμ in electron micrographs (Rake *et al*, 1946, Kurotchkin *et al*, 1947) In a later study, Hamre, Rake, and Rake (1947), using purified allantoic fluid, found the EB had a *dense central area, and a surrounding thinner substance, like a membrane, groups of EB* appeared enmeshed in a matrix, the mean diameter was 525± 84mμ

2 The virus is not markedly sensitive to sulfonamides (Hamre and Rake, 1944, 1947, Rake and Hamre, 1944, Eaton and Hanford, 1945) Streptomycin and streptothricin had no effect *in vitro* or *in vivo* on the virus (Hamre and Rake, 1947) They found high concentrations of penicillin active *in vitro*, activity appeared to be associated with some impurity When tested in the yolk sac, penicillin delayed death of the embryos

3 The virus produces a specific toxin which is neutralized only by homologous serum *(Hamre and Rake, 1944, Hamre, Rake, and Rake, 1947) The toxin is not sensitive to* sulfonamides (Rake and Hamre, 1944)

4 Hamre and Rake (1944) point out that the virus can be distinguished from other pneumonitis viruses by its ability to infect mice nasally, intravenously, peritoneally and cerebrally, by its insusceptibility to sulfonamides, and by the specificity of its toxin

5 Its antigenic relationships are discussed above

Miscellaneous Pneumonitis Viruses

A number of viruses producing pneumonia in animals have been described, but have not been studied sufficiently for us to classify them with certainty, although many belong to the basophilic pneumonitis group a virus causing pneumonia and hepatitis in mice (Freeman, 1940), other agents producing pneumonia in mice have been described (Gonnert, 1941, Gross, 1943 *a, b, c*, Karr, 1943, Mooser, 1943, Furth and de Gara, 1944, Thomas and Kolb, 1944, Aufdermaur, 1945, deBurgh, Jackson, and Williams, 1945), a virus producing pneumonia in calves (Baker, 1943), viruses producing pneumonia in hamsters and cotton rats (Pearson and Eaton, 1940, Eaton and van Herick, 1944, Eaton *et al*, 1945), the

[1] References are appended at the conclusion of Ch LXIX, p 733 et seq

3. It grows in the yolk sac

4 It resembles most closely MP and psittacosis viruses, but is distinguished from these by its higher pathogenicity for guinea-pigs, and for mice by the subcutaneous and muscular routes

Miscellaneous Viruses of Presumed Human Origin

A number of basophilic viruses have been isolated by inoculation of material from cases of AP in animals, but for various reasons have not been much studied It is not clear whether they derived from the inoculated animal or the human seed, nor is their relationship to the better known members of the pneumonitis group certain (Reimann, 1938, Herzberg and Gross, 1940, Heinzmann, 1941, Rose and Molloy, 1943).

Weir and Horsfall (1940) isolated a virus by inoculation of mongooses, but Dammin and Wheller (1945) could not infect these animals

Kempf, Wheeler, and Nungester (1945) isolated Ann Arbor virus from hamsters inoculated with human throat washings It infects mice nasally, and antisera can be prepared in roosters It shares an antigenic component with mouse pneumonitis virus (St John and Gordon, 1947, see Table 32)

a size of 40mμ (if spherical). The principal hydrated particles of combined virus have a diameter of 140mμ.

The following are the chief properties of the 4 states in which PVM may occur.

State of Virus	*Infectivity for Mice*	*Hemagglutination Unheated*	*Heated*
Free infectious	+	+	+
Free noninfectious	o	+	+
Combined infectious	+	o	+
Combined noninfectious	o	o	+

4. The virus is neutralized by about 30 per cent. of normal human sera (Horsfall and Hahn, 1940), and by sera from many animals (Horsfall and Curnen, 1946 *a*, *b*). It appears that infection with this agent is widespread, and it seems reasonable to conclude it is an occasional cause of human pneumonia

5. Streptococcal cultures given nasally 2–3 days before, or 1–4 days after nasal inoculation of virus in mice resulted in marked inhibition of virus multiplication in the lungs. Further experiments showed that the active substance was probably polysaccharide. Then it was found that certain other polysaccharides of bacteria (especially Friedlander's bacillus), and of nonbacterial origin were also capable of inhibiting the multiplication of virus in the lungs of mice The effect may be due to competition with PVM for some essential growth system (Horsfall and McCarty, 1947).

6. Tubercular lesions of the lungs in mice were enhanced if the animals were infected with PVM or influenza virus as well (Volkert *et al*, 1947).

The SF Virus

The San Francisco (SF) virus was isolated in 1940 from the lungs of 2 fatal and the sputum of 2 nonfatal cases of atypical pneumonia, and has been isolated from other cases (Eaton, Beck, and Pearson, 1941, Beck and Eaton, 1942; Meiklejohn, Beck, and Eaton, 1944).

1. Electron micrographs show the particles to measure 422 ± 58mμ (Kurotchkin *et al.*, 1947).

2. It infects mice nasally and cerebrally, but does not kill by the peritoneal route Cotton rats, hamsters, and guinea-pigs can be infected (see Table 31). It is of low virulence for Java rice birds The virus does not produce the carrier state in mice or birds. It grows in the allantoic cavity (Francis and Gordon, 1945).

3. The virus is antigenically related to other members of the group, but occupies a fairly distinctive position (see above).

The Illinois Virus

Zichis and Shaughnessy (1945) isolated a pneumonitis virus from the lungs of 2 fatal cases of pneumonia by mouse inoculation. It was related to but distinct from SF. It was different from psittacosis, ornithosis, or MP.

The Louisiana Virus

This virus was isolated from an outbreak of AP in the Bayou region of Louisiana (Binford and Hauser, 1944, Olson and Larson, 1944, 1945, Olson and Treuting, 1944, Treuting and Olson, 1944, Fite, Larson, and Olson, 1946, Larson and Olson, 1946).

1. Autopsy of human cases showed pulmonary consolidation, infiltration of the alveoli with large mononuclear cells, hyperplasia of the alveolar lining cells, with at most slight involvement of the bronchioles and bronchi A few basophilic cytoplasmic inclusions were found in the pulmonary alveoli

2. The virus is readily transmissible to mice, guinea-pigs, and cotton rats, by the peritoneal route White rats, hamsters, and deer mice are not so susceptible

Physical examination may detect moist sounds, dullness, and altered breath sounds in the lungs, pharyngitis, the temperature usually varies between 100° F. and 103° F for 7–10 days, and falls by lysis.

Atypical pneumonia may occur in association with malaria (Campbell, 1943; Applebaum and Shrager, 1944, Fleming, Lindeck, and Evans, 1945). Complications include pleural effusion and skin rashes Bronchiectasis has been reported (Blades and Dugan, 1943, Kay, 1945, Nalls, 1945, Schmitz, 1945), also pericarditis (Finkelstein and Klainer, 1944). Nervous complications may occur, such as polyneuritis, serous meningitis, meningomyelitis, and encephalitis (Campbell *et al*, 1943, Sheppe *et al.*, 1943; Noran and Baker, 1946, Holmes, 1947).

The fatality rate is not over 0.1 per cent, although it may be more severe (Golden, 1944, Higley, Warren, and Harrison, 1944)

CLINICAL PATHOLOGY

There is not usually any significant change in the total or differential white count, but there may be a relative increase in mononuclears. Some workers have described an increase in the BSR, but others have not found the test of value (Willcox, 1943, van Ravenswaay *et al*, 1944, *Commission*, 1946, Painton, Hicks, and Hantman, 1946) The cephalin-cholesterol flocculation test is said to be positive (Adams *et al*, 1946) Hypo-amino-acidemia does not occur (Emerson *et al.*, 1943).

The serum may develop a capacity to fix complement with various crude tissue antigens (Thomas *et al*, 1943 *a*), and heterophil antibodies for horse cells have been described (Adams *et al*, 1946)

"Cold" agglutinins develop in the sera of half to a third of all cases, and have been studied by many workers (see, e g, Dameshek, 1943, Hortsmann and Tatlock, 1943, Meiklejohn, 1943, Peterson, Ham, and Finland, 1943, Shone and Passmore, 1943, Turner, 1943, Turner and Jackson, 1943, Turner *et al*, 1943, *Commission*, 1944 *a*, 1946, Heintzelman and Seligmann, 1944, Humphrey, 1944, Rich, Rae, and McGoey, 1944, Siffert and Krautman, 1944, Streeter, Farmer, and Haynes, 1944; Eaton, 1945, Erf, 1945, Finland, Peterson, and Barnes, 1945, Finland *et al*, 1945, Florman and Weiss, 1945, McNeil, 1945, Meiklejohn, Eaton, and van Herick, 1945, Springarn and Jones, 1945, Abernethy, 1946, Hegglin, 1946, Young, 1946, Eaton and van Herick, 1947 *a*)

1 The hemagglutinin operates at about 0° C It is completely independent of the blood group isohemagglutinins. In diagnostic tests, human group o cells are used

2 Similar agglutinins may develop in other conditions, but titers of 1/64 or more are seldom found except in cases of AP, in general, the severer the illness the higher the titer The test first becomes positive 4–8 days after onset, and the maximal titer is usually reached between the 16th and 23rd days. A fourfold or greater increase is very rare except in AP (*Horsfall*, 1947) The test is usually negative after 4–6 weeks

3 The agglutinin is destroyed at 66° C in ½ an hour, and may be removed by filtration (Finland, Peterson, and Barnes, 1945).

4 There is some risk that under certain conditions an intravascular hemolytic reaction may occur, owing to agglutination and lysis of red cells (Dameshek, 1943, Helwig and Freis, 1943, Finland *et al*, 1945, Platt and Ward, 1945).

5 Cold agglutinins do not develop in all cases of apparently typical AP, and pending clarification of the etiology, Williams (1947) has suggested that a distinctive group can be recognized, characterized by patchy radiological shadows, migration of the pneumonic process from one lobe to another, and the presence of cold agglutinins to a titer of 1 64 or over

Streptococcal agglutinins The sera of up to half the cases of AP develop agglutinins for various "indifferent" streptococci, such as the MG or 344 strains (Thomas *et al*, 1943 *b*, Meiklejohn and Hanford, 1944, Finland, Samper, and Barnes, 1945, Eaton, 1945, Florman and Weiss, 1945, Abernethy, 1946, Eaton and van Herick,

CHAPTER LXIX

PRIMARY ATYPICAL PNEUMONIA (AP)

For many years, clinicians have from time to time described cases of consolidation of the lungs, *differing markedly from the classical lobar (pneumococcal)* pneumonias or from bronchopneumonias. These cases seem to have become more common in the last 10 years, and the subject has attracted much attention (see, e g, Reimann, 1941, 1943, Beeson, 1943, Drew, Samuel, and Ball, 1943, Favour, 1943, Smadel, 1943, Francis, 1944; Moore, Wightman, and Showacre, 1944; Dingle, 1945; Lembcke and Young, 1945, Curnen, 1946).

The etiology of nonbacterial pneumonia is obscure. It appears that in about 25 per cent. of cases, the causal agent is a basophilic virus of the psittacosis-ornithosis-pneumonitis group. Certain other viruses may produce a similar clinical picture, for example, *lymphocytic choriomeningitis (Reimann, Havens, and Price, 1942)*, and influenza. A similar form of pneumonia may be produced by *Rickettsiae*.

However, the bulk of cases is not due to these agents, and the cause awaits discovery. There is little doubt, particularly after the careful experiments of the *U S. Commission* (1946), that the causal agent of the common form of nonbacterial pneumonia is a filtrable virus.

There exists a group of milder infections of the upper respiratory tract, and some of these cases may well be caused by the same virus as produces nonbacterial pneumonia (see, e.g., Iverson, 1943, *Commission*, 1944 *b*, *c*)

As the etiology of mild nonbacterial pneumonia is uncertain, terminology cannot but be confusing Those cases produced by psittacosis and ornithosis virus should be described as psittacosis or ornithosis Cases produced by Louisiana, SF, or other viruses may be described as "virus pneumonias" produced by these agents Most cases, in which the causal agent is unknown, are usually now described as "primary atypical pneumonia" (AP), and the addition "etiology unknown" may be used to obviate confusion with other virus pneumonias The unqualified term "virus pneumonia" is too general to be of much value, and could include infection by the viruses of psittacosis, ornithosis, pneumonitis, influenza, and measles, as well as infection by the yet undiscovered virus of AP

We see no reason why the term "pneumonitis" should be used instead of the time-honored "pneumonia" Unfortunately, the term has come to stay as regards certain basophilic viruses of human and animal origin related to psittacosis.

CLINICAL FEATURES

The clinical features have been described by many different workers (e g, Brown *et al.*, 1942– [illegible] Engelhardt and Wilen, 1942, Goodrich and Bradford, Heyden, 1942, Riven and *Stern, 1942*, B 1943, *1944 a*, Drew, Samuel, and Ball, 1943, Haight and Trolinger, 1943, Meakins, 1943, Montgomery and Shore, 1943, Young, Storey, and Redmond, 1943, Favour, 1944, Fraser, 1944, Gundersen, 1944, Higley, Warren, and Harrison, 1944, Hobby, 1944, Sachs, 1944, Smith, 1944, Breslow, 1945, *Commission*, 1945 *a*, 1946, Curnen *et al*, 1945, Fuchs, 1945, Grossman, 1945, Karpel, Waggoner, and McCown, 1945, *Abernethy, 1946*, McDonald and Ehrenpreis, 1946)

The onset is usually gradual, with influenza-like or upper respiratory symptoms including chills, anorexia, and headache Local symptoms include nasal stuffiness, sore throat, dry paroxysmal cough, mucoid sputum, and pain in the chest or abdomen

1944 *c*, Erickson and van Ravenswaay, 1944, Owen, 1944, Tumulty, 1944, Glendy, Beaser, and Hankins, 1945, Turner, 1945; Abernethy, 1946, Adams *et al*, 1946).

EVIDENCE FOR A VIRUS ETIOLOGY OF AP

Clinically, the condition that we describe as primary atypical pneumonia is distinctive, and not to be confused with bacterial pneumonia. The x-ray changes may be regarded as more suggestive of a virus than a bacterial pneumonia No worker has succeeded in proving the rôle of any cultivable bacteria or other agent in the disease In fact, there seems little doubt that the condition is due to a filtrable virus. That this is so, has been proved by the elaborate experiments of the U S. *Commission* (1945 *b*, 1946, 1947; Dingle, 1945). This group showed that the disease can be transmitted to volunteers by sprays of filtered (and unfiltered) throat washings and sputa of typical cases The incubation period was found to be 8–14 days, being longer when filtrates were used The illness was typical of the naturally occurring disease Cold agglutinins developed in most cases, and streptococcal agglutinins in some instances

In a number of cases, a less severe form of minor respiratory illness developed This suggested that the same virus might cause a gradation of symptoms

As yet, no reports on the characters of the filtrable agent incriminated by the Commission have appeared

The Virus of Atypical Pneumonia

This virus has been isolated by Eaton and his collaborators, from sputum and lung suspensions of cases of AP (Eaton *et al.*, 1942, 1945; Eaton, Meiklejohn, and van Herick, 1944; Eaton 1945, Eaton, van Herick, and Meiklejohn, 1945; Eaton and van Herick, 1947 *a*, *b*).

The virus is transmissible to cotton rats, hamsters, and chick embryos, the particle diameter lies between 180–250 mμ

It has proved possible to immunize hamsters and cotton rats by injections of live or formolized virus.

This virus would seem to be of definite importance, as specific neutralizing antibodies have been found in the convalescent sera of a considerable number of cases in different outbreaks of clinically typical AP in both eastern and Pacific parts of America These sera have also contained cold and streptococcal agglutinins

PNEUMONITIS IN INFANTS

Adams and coworkers described a variety of primary pneumonia occurring in infant nurseries (Adams, 1941 *a*, *b*, 1943, Adams *et al*, 1942) The infection was highly contagious, and affected the very young. The incubation was about 7 days The affected babies had a cough, and showed dyspnea and cyanosis There was a low pyrexia About 25 per cent died of hemorrhagic pneumonia Cytoplasmic inclusions were found in the bronchial epithelial cells Ingleby (1944) found similar inclusions in various organs

Goodpasture *et al* (1939) described nuclear inclusions in the tracheal and bronchial epithelium of infants

No definite viruses were, however, isolated by the above workers.

1947 *a*). Agglutinins for these streptococci develop more commonly and to higher titer in the sera of cases of AP than in other conditions. The streptococcal agglutinin is unrelated to the cold hemagglutinin. A fourfold or greater increase is only rarely found except in AP (Horsfall, 1947).

Although nonhemolytic streptococci can be isolated from the respiratory tract of cases of AP, there is no evidence that any particular serological group is causally associated with the disease (Dingle *et al.*, 1944 *b*; Thomas *et al*, 1945); the significance of the presence of these agglutinins is, therefore, obscure.

Laboratory diagnosis. Some of the laboratory tests required will be evident from what has be[illegible]
be refrigera[illegible]
to isolate a [illegible]
and by inoculation of yolk sacs, complement fixation tests with psittacosis or LGI antigens, and perhaps the Frei test will help to exclude those cases due to basophilic viruses. Ziegler *et al* (1947) have pointed out that for the accurate diagnosis of AP, a very full series of laboratory tests is required, including tests for influenzal infection, for pneumococci, for streptolysin, as well as the tests mentioned above. Using such a system to investigate a group of cases of respiratory infection, they found that AP and influenza might occur together, and that cases classified clinically as AP often turned out to be pneumococcal in origin.

RADIOLOGY

The appearances, although not diagnostic, are most helpful, and certain cases can be diagnosed only by this means (Fredd, 1941, Duggan and Powers, 1942, Campbell *et al*, 1943, Correll and Cowan, 1943, Haines and Forcey, 1944, Kruger *et al*, 1944, Showacre, Wightman, and Moore, 1944, Yoskalka, 1944, Abernethy, 1946, Crysler, 1946, McDonald and Ehrenpreis, 1946).

The changes usually occur unilaterally, and various appearances have been described a wedge or fan-shaped infiltration in the lower lobe, with its apex at the hilus; patches of irregular opacities, and even up to miliary lesions, peribronchial infiltrations, reticulation radiating from the hilus, apical lesions may occur resembling those of tuberculosis. Changes suggestive of peribronchial fibrosis may persist for several months X-ray therapy has been claimed to be effective (Correll and Cowan, 1943)

PATHOLOGY

Comparatively few reports of pathological investigations have appeared (Campbell *et al*, 1943, Perrone and Wright, 1943, Golden, 1944, Lusk and Lewis, 1944) The lesions are essentially those of an acute interstitial pneumonia The chief changes include bronchitis, bronchiolitis, peribronchitis, and peribronchiolitis Mononuclear infiltration is common Atelectasis is caused by a mechanical obstruction of the bronchi and bronchioles Microscopically, the alveoli contain mononuclear and polymorph cells, with fibrin A secondary bacterial invasion may occur

EPIDEMIOLOGY

The disease seems to affect chiefly young adults, mainly males It occurs in all parts of the world, including the tropics (see, e g, Bower, 1943, Leake and Blatchford, 1943) It has been suggested that there are seasonal peaks of high incidence in November or March.

The disease is less common in "seasoned" troops than in new recruits (*Commission*, 1944 *b*). During the second World War, AP was responsible for a considerable temporary loss of manpower, and in this respect was probably more important than bacterial pneumonia (Markham, 1942, Moore, Tannenbaum, and Smaha, 1942, Campbell *et al*, 1943, Drew, Samuel, and Ball, 1943, Frachtman, 1943, *Commission*,

CHAPTER LXX

PSITTACOSIS

Introduction

JUERGENSEN (1874)[1] is credited with being the first to recognize the disease psittacosis as a distinct clinical entity manifesting itself as an atypical form of pneumonia. Later it was referred to as "pneumotyphus" by Ritter (1880) and Wagner (1884, 1888).

It occurred in Paris in 1892, and Morange (1895), who studied cases in France, proposed the name of "psittacosis" for the malady. At this time Nocard (1893) claimed to have discovered the cause of the condition, and isolated a bacillus from fatal cases of the illness

It was not until the 1929–30 outbreak that Lillie (1930) in America, the British microscopist Coles (1930), and Levinthal (1930 *a*) in Germany discovered almost simultaneously the presence of minute intracellular bodies within affected reticulo-endothelial cells. Subsequent researches of Bedson (1930), Gordon (1930), and Bedson and Bland (1932) firmly established the etiological relationship of these structures to the malady, and further revealed that the virus exhibited a cycle of morphological changes when growing in animal tissues. Owing to its general resemblance to the *Rickettsiae*, Lillie (1930) has called the parasite *Rickettsia psittaci*, and Coles (1930) likewise stressed its resemblance to the *Rickettsiae*. Such a designation is not desirable, however, for it implies that the agent is associated at one stage of its life history with an arthropod vector, and this has not been proved.

The term *Mycobacterium multiforme psittacosis* proposed for it by Levinthal (1930 *c*) is also unsatisfactory.

In the following pages we propose to refer to the agent as the virus of psittacosis; we have also adopted the name of Levinthal-Coles-Lillie body, or LCL body, to describe the inclusion body stage of the virus

For information regarding the general aspects of this disease the reader is referred to the work of Bedso [illegible] (1932), Meyer, Eddie, and Stevens (1935), Rivers [illegible] (1937), Meyer (1937, 1942), Cardona (1937), Bar [illegible] (1944)

Psittacosis is one of the varieties of virus pneumonia It has been estimated that about 25 per cent of cases of sporadic atypical pneumonia are due to psittacosis (Smadel, 1943) The antigenic relationships in the LGI-psittacosis-pneumonitis group are described in Chapter LXVII.

EPIDEMIOLOGY

Some Early Outbreaks of Psittacosis (before 1929)

1879	Switzerland	Ritter (1880), Eberth (1880)
1882	Leipzig	Ost (1883), Wolff (1883)
1882	Bonn	Finkler (1888)
1892	Paris	Gastou (1892), Morange (1895), Du Jardin-Beaumetz (1892)
1895	Florence.	Palamidessi (1895)
1895	Prato and Genoa	Malenchini (1896)
1896	Paris	Dupuy (1897), Gilbert and Fournier (1896), Nocard and Debove (1896), Sicard (1897)
1897	Genoa	Maragliano (1897)
1898	Stettin	Haedke (1898).
1904	Brazil	Souza (1904)

[1] References are appended at the conclusion of Ch LXXI, p 758 et seq

isolated, but in some of them, although the spleen was not pathogenic to mice, the organ was found to be greatly enlarged and this was accordingly interpreted as a sign of past infection The virus has also been isolated from Australian shell parakeets by Meyer and Eddie (1934), who found that freshly isolated strains were at first feebly pathogenic to mice, but after repeated passage they could be exalted in virulence, and typical LCL bodies were then demonstrable in the spleens of infected animals. Two strains of virus isolated from Australian parrots of the species *Psephotus haematonotus* and *Platycercus eximmo* have been successfully cultivated in the chorio-allantoic membrane of the developing chicken embryo by Burnet and Rountree (1935).

Later, Burnet (1939) isolated virus from wild parrots in Victoria, Tasmania, and S Australia (see also Meyer and Eddie, 1939 *b*). Finches may be infected (Tremain, 1938). Geiger *et al.* (1939) found the following infected *Alisterus*, *Platycercus*, *Nymphicus hollandicus*, *Kakatoe sanguinea*, and *Kakatoe galerita*.

Conclusions: Species of Bird Affected

At least 50 species, comprising 5 orders of the class *Aves* may be infected spontaneously with psittacosis (Meyer, 1942). The bulk of infection seems to be in Australia and S America So far, Indian parrots appear to be free of infection (Goyal, 1940)

The Mode of Spread of Psittacosis

During the last epidemic of the disease, which occurred in 1929–30, a number of important points were reestablished concerning the epidemiology of psittacosis, the most outstanding of which was the fact that the appearance of the human disease was preceded by an epizootic among parrots, probably in Brazil (see Roubakine, 1930). Many of the birds which were imported by dealers into the Argentine, Great Britain, and the Continent died during transit, or else shortly after arrival at their destination Weltmann (1929), for example, states that out of a consignment of 157 Brazilian parrots which arrived at Bremen during the end of July 1929, only 40 survived the journey to Vienna. Thirty of these were bought by an American and the remaining 10 by other persons, in each of whose households cases of psittacosis subsequently developed. A somewhat similar state of affairs was experienced in the Paris outbreak of 1892, when 2 bird dealers purchased 500 parrots from Buenos Aires and only 200 of the creatures were delivered alive in Paris

At one time the facilities offered on board ship for the conveyance of birds were extremely insanitary (see Wolff, 1883, Pitman, 1927, Bannerman, 1927, and Heymann, 1930), but even although livestock transport arrangements are much improved to-day, a great number of birds perish *en route*

Adverse conditions, such as chilling and wetting, act by causing the disease to become active in birds latently infected Such carriers become sick and excrete virus, *infecting others previously healthy*

Spread of infection from parrot to parrot.

Theoretically any object which has been in contact with an infected parrot is potentially capable of infecting another bird. Thus, healthy stock are liable to catch the disease if placed in infected cages [illegible] saliva, droppings, or urine of sick parro[illegible] have demonstrated the presence of the [illegible] also possible that the virus may sprea[illegible] surroundings or in captivity, as the result of direct mouth-to-mouth contact.

Spread of infection from parrot to man.

Probably the majority of human cases of psittacosis has been contracted by bird owners and others who touch the cages or handle the plumage of infected

Species of Birds known to Transmit Infection

In his survey of the literature on human *psittacosis*, Roubakine (*1930*) stated that up to that time nearly all the described cases of psittacosis had been caused by parrots originating from the Amazon district of Brazil. Most of the cases were c[illegible] *cus*, known as the "[illegible] was the home of t[illegible] id disease among birds transported from the tropics. He stated that because in the 1929-30 epidemic the condition appeared synchronously in Argentina, Algeria, Germany, Austria, England, Holland, Czechoslovakia, Denmark, Switzerland, France, Spain, Portugal, Canada, Hawaiian Islands, and the United States, he considered it improbable that so world-wide a distribution could spring from a single country of origin. In view of these conflicting opinions, the origin of the 1929–30 outbreak cannot be definitely located. The bulk of evidence is in favor of South American birds being the source of infection, and that the 1929–30 cases in man were preceded by an epizootic among parrots in Brazil At this time psittacosis was an unknown disease in Australia, consequently birds imported from this continent were exempt from suspicion (*vide infra*) (see Elkeles and Barros, 1931).

Parakeets, "love birds," and canaries have also been found infected (Meyer and Eddie, 1933 *a*, Rosenbusch, 1937). Thus the Zulpich epidemic of 1909 was due to the grass parakeet *Melopsittacus undulatus;* thrushes and the Italian cardinal bird have been blamed by Barros (1929). Budgerigars have been incriminated by Swan and Dawson-Walker (1939) and others.

Forest psittacines (*Myiopsitta monacha* Bodde) have been found infected in South America (Parodi and Silvetti, 1946).

Psittacosis in Australia

At one time it was believed that the disease was absent in Australia, but later Meyer and Eddie (1934), in California succeeded in isolating the virus from a consignment of 200 Australian shell parakeets which they had imported from Sydney. Investigations were next set on foot to discover whether the disease existed among Australian birds living amid their natural surroundings, as a result of which Burnet (1934) succeeded in recovering the virus from a number of birds purchased in Adelaide and Melbourne No human cases were, however, observed at the time, and in an article dealing with this subject in *Health* (1936) it was pointed out that the apparent absence of human cases in Australia was probably attributable to the fact that, since the strains of virus isolated from Australian parrots were found to be feebly pathogenic to mice, they were, in all probability, also equally avirulent to man. Following these observations, a careful watch was kept for the occurrence of human cases in Australia, and Kennedy (1936) demonstrated the virus in the sputum of one patient suffering from the disease Ross and Rabinov (1936) subsequently reported 7 cases of infection acquired through contact with sulfur-crested cockatoos of the species *Cacatua galerita*, and Burnet and Macnamara (1936) stated that there were approximately 17 human cases in the State of Victoria, Australia, from 1935 to 1936 In 2 instances the disease was traced to contact with aviary-bred budgerigars of the species *Melopsittacus undulatus*, and in the remainder to sulfur-crested cockatoos (see also Merrillees, 1934, and Cumpston, 1936)

Burnet (1935) has proved the presence of latent psittacosis infection in the spleens of several of the commoner species of Australian parrot The virus could be recovered from these birds by removing the spleen, emulsifying it in broth, injecting the material into mice and thereafter examining the spleens of the latter for evidence of LCL bodies. By this method Burnet succeeded in isolating strains of psittacosis virus from the *Psephotus haematonotus*, *Trichoglossus*, and *Leptolophus hollandicus* varieties of parrot From other species the virus was less frequently

to mice, and it is conceivable that these may be able to infect human beings and particularly laboratory workers who fail to take adequate precautions to safeguard themselves against infection (see McCoy, 1934).

Quarantine Measures

To obviate the risk arising from the importation of infected stocks of birds, quarantine of up to 6 months should be imposed on all shipments of psittacines. During this period, the infected animals usually become sick. This quarantine procedure is abundantly justified. For example, in a shipment of over 100 Amazon parrots and parakeets quarantined in Texas, no less than 97 per cent. died (Dunnahoo and Hampton, 1945).

Geiger *et al.* (1939) draws attention to the following points

1. Clinical examination alone is useless to detect infection
2. Laboratory examination is specially indicated if deaths have occurred in transit.
3. Enlargement of the spleen is suggestive of infection
4. The highly susceptible rice bird (*Padda oryzivora*) should be distributed in cages about the quarantine house, to act as an indicator of "shedding" of virus.

A useful practice is to examine a definite proportion of the shipment by autopsy, and carry out virus isolations and serological tests

CLINICAL FEATURES OF PSITTACOSIS

The *incubation period* ranges from 6 to 15 days, and is generally 10 days in the majority of cases, but sometimes may be as long as 30 to 82 days (see Gulland, 1924, Armstrong, 1930).

Onset is often sudden, and the illness may be ushered in by a chill, sore throat, headache, or vomiting, followed by signs of general malaise, such as insomnia and delirium. Either diarrhea or constipation may be evident at this stage In the case of individuals who have contracted infection as the result of feeding the animals with their mouths, circumoral edema has been noticed Other clinical manifestations are furring of the tongue, loss of appetite, abdominal distension, epistaxis, or stupor

Sex Females are more frequently affected than males, but this difference is probably attributable to the fact that women are more often exposed to infection than men For example, during the course of their domestic duties they spend a good deal of time at home, in the proximity of infected birds, and are particularly liable to acquire infection during the act of feeding the animals or cleaning out their cages

Age is an important factor in determining the prognosis of a case Armstrong (1930) stresses the fact that children and young adults suffer from milder attacks of the disease than their elders, and in a series of 169 cases investigated by him he found that no deaths occurred among 35 persons under 30 years of age, whereas the mortality rose to 24 per cent in individuals over that age Thomson and Hillier (1930) have also commented upon the resistance of young children to infection and state that when they do develop the disease they experience less severe symptoms than adults

Symptomatology

Lung lesions.

Pulmonary changes are a characteristic feature of human psittacosis, but they may or may not be detectable at the onset of the illness, and their existence is not necessarily a bad prognostic sign At first the patient's signs and symptoms resemble those of a mild attack of bronchitis, and the clinician may diagnose the case as one of early lobar pneumonia Later, however, about the end of the first 7 days, various points of distinction become apparent, and the absence of a malar flush, persistent

birds, such as is unavoidable when cleaning out cages or perches. In other cases there may be no record of the individual having handled the bird himself, and in such instances infection has been traced to respiratory droplet infection, due to the person having been near to the animal when it was speaking or screeching Lastly, infection has been acquired by certain bird fanciers who practice the objectionable habit of feeding their pets directly out of their own mouths. To do so with an infected bird is obviously to invite disaster. The feathers and wings of dead birds can convey the virus to taxidermists, milliners, and others.

It must be emphasized that birds may not appear to be ill at all, but may be carriers of the infection and "shedding" virus

Infected material, in the form of dried particles, is abundant in the feathers of birds The risk to man is by inhalation of such particles, or droplets of respiratory secretion.

Psittacosis has occurred in the staffs of zoological gardens, and such workers should wear masks and goggles (Troup, Adam, and Bedson, 1939, Tomlinson, 1941).

Spread of infection from man to man.

Man-to-man infection sometimes occurs, but is a comparatively rare event Cases of disease acquired by those in contact with patients such as nurses, doctors, visitors, and others have been reported in the literature by Armstrong (1930) in America, by Bedson, Western, and Simpson (1930) in England, and by Gunther (1930) and Hegler (1930) in Germany. Lillie (1933) demonstrated EB's in the alveolar secretion, accordingly, the case must be treated as infectious (see Pfaffenberg, 1936).

Human carriers of psittacosis virus.

Gerlach (1936 *b*) has described 5 cases of latent infection in whom the classical signs and symptoms of the disease were absent. In none of these individuals could the infection be traced to contact with birds In 2 instances there was a history of contact with other cases of psittacosis in hospital, and in 2 others the virus was discovered fortuitously during the conduct of a search for carriers among a group of 50 unselected patients On one occasion the virus isolated was so feebly pathogenic to mice that it was necessary to passage it serially through 6 sets of animals over a period of 6 weeks before it produced recognizable inclusion and elementary bodies in the spleen. In another case the agent was recovered from the patient's blood on the 72nd day, and from the sputum on the 75th day after the diagnosis had been originally established Gerlach's findings are of considerable interest, since they illustrate the important fact that human psittacosis is not invariably accompanied by recognizable clinical signs and symptoms or evidence of a severe illness The work, furthermore, emphasizes the importance of regarding all individuals engaged in the handling of parrots, parakeets, and other varieties of exotic bird as possible carriers of infection The necessity for repeated passage of the virus in mice before recognizable lesions are produced in the animals is also made clear

Laboratory infections.

These infections have been described An interesting case was that of Rosebury *et al* (1947 *a*) where the source was a faulty ampule More usually infection is contracted during the manipulation of suspensions or the inoculation of animals or eggs

The Rôle of Other Animals in the Spread of Psittacosis

Monkeys are susceptible to experimental inoculation with the virus, and it is quite possible that in captivity they may become infected from birds, and then convey infection to human beings (see Lons, 1930) The virus is also pathogenic

publications of Kerschensteiner (1930), Lons (1930), Rivers, Benjamin, and Berry (1930), and Johnson and Levinthal (1935).

Pulse and respiration rate are usually increased, and the rise may be considerable in severe cases

Relapses sometimes occur. In the 11 cases reported by McCoy (1930) affecting laboratory workers, 3 suffered from relapses within 3 weeks after their temperature had subsided to normal, and another patient experienced a relapse after 4 weeks. All 4 relapses occurred among patients who had been treated with convalescent serum during their illness

Complications Thrombophlebitis has been known to occur, and a common cause of death appears to be pulmonary thrombosis (Armstrong, 1930, Rabinowitz and Livingstone, 1932; Badger, 1934).

MORTALITY

The mortality figures reported by independent observers during different epidemics of psittacosis have fluctuated considerably Dupuy (1897) stated the death rate to be 34 per cent. among 70 cases observed by him over a period of 4 years in Paris Armstrong (1930) examined the case records of 169 patients during the American outbreak of 1929–30, and found the mortality to be 19 per cent, and Nocht found the figure to be 35 per cent among 20 cases of psittacosis observed by him in Hamburg Altogether from July 1929 to February 1930, Heymann (1930) estimated that a total of 350 to 400 cases was notified throughout America and Europe and of these 35 to 40 per cent. died

All races of mankind appear to be equally susceptible to psittacosis infection, and there are no reasons to believe that different individuals possess either racial or natural immunity to infection It is nevertheless a curious fact that although the disease is enzootic among parrots in Brazil, fewer human cases appear to have been described by clinicians from this part of the world than elsewhere (see Souza, 1904, Roubakine, 1930)

CLINICAL PATHOLOGY

The leukocyte count in psittacosis has been investigated by Krumeich (1930) and his results show that the white count is usually normal at the beginning of the illness, but later a transient leukocytosis may occur, followed by a leukopenia. Sturdee and Scott (1930) maintain that the leukocyte count is normal or subnormal in 75 per cent of cases, and that leukopenia is present in only 25 per cent of the patients In the cases studied by Armstrong (1930) the white count fell to 3,000–5,000 cells, and in one case a reading of 500 leukocytes per c mm was observed on the 20th day of the patient's illness (see also Rivers, Benjamin, and Berry, 1930, Thomson and Hillier, 1930, and Peterson, Spalding, and Wildman, 1930) The red cell count sometimes shows a slight fall at the height of the febrile period, but is usually within normal limits.

Albuminuria is commonly present during the febrile period

PATHOLOGY

The Respiratory System

The lungs.

The postmortem appearances naturally depend on the stage of the illness at which death occurs If it takes place on or about the 13th day of the illness, then the lungs are congested, and gray or grayish-red consolidation may be seen. The *pleurae* are smooth, they exhibit petechial hemorrhages, and a turbid serofibrinous exudate may be present (see Horder and Gow, 1930, Scholte, 1930, Krumeich, 1930)

The *nature of the consolidation* found in parrot disease has been carefully in-

coughing, and profuse expectoration enable the condition to be differentiated fror typical lobar pneumonia.

Physical examination of the chest On inspection, seen after the first week, ther may be unilateral limitation of thoracic movement. On palpation and percussio there may be pain, and other signs of pulmonary involvement can be elicited. Th earliest demonstrable changes may be confined to an area of dullness on percussio at one or other base, which may spread to involve other parts of the same organ or extend to the opposite side.

On auscultation over the affected area normal breath sounds are replaced b bronchial or tubular breathing, and this is soon followed by complete absence o all sounds and indications of generalized pulmonary consolidation Crepitations ar usually heard at the base and moist râles may be audible in other areas surroundin the focus of damaged lung (see Gulland, 1924; Thomson and Hillier, 1930, Kummerling, 1937). Gross-Hardt (1935) has given an account of the clinical finding and diagnosis of 7 cases.

In general, the lung lesions found in psittacosis tend to be patchy in their distribution, and from the results of physical examination they present the characteristics of multiple bronchopneumonic areas of consolidation, rather than the physical signs of a true lobar pneumonia. In cases in which recovery occurs, the pulmonary lesions may last throughout the course of the patient's febrile period and may even persist for some time afterward during convalescence

Pleural effusions have been reported by certain observers. Gulland (1924) removed about 10 oz. from a case studied by him, and found that it contained no cultivable bacteria. Thomson and Hillier also noticed pleuritic effusions in certain of the cases under their care. Rabinowitz and Livingstone (1932), on the contrary, remarked that even although extensive pulmonary consolidation was present in the cases studied by them, no evidence of pleural involvement could be elicited, and Maclachlan, Permar, and Rogers (1930) reported similar findings

X-ray examination of the chest has been carried out by Peterson, Spalding, and Wildman (1930), who have demonstrated the presence of pulmonary consolidation during life by radiographic methods (see also Rabinowitz and Livingstone, 1932, and Stehr, 1935).

Other signs and symptoms.

The skin. Horder and Gow (1930) reported the presence of a rash in one of the cases under their observation A colored illustration depicting the nature of this rash is to be found in the work of Sturdee and Scott (1930)

Central nervous system Several clinicians have reported the presence of headache, drowsiness, apathy, and mental depression during the course, and immediately following an attack of psittacosis (see Gulland, 1924, Rabinowitz and Livingstone, 1932).

Alimentary system The tongue is furred, being white at the onset and brown later during the disease, the throat is congested Either constipation or diarrhea may be present Physical examination of the abdomen may reveal no characteristic findings, but Horder and Gow (1930) reported the presence of abdominal distension about the 3rd week of illness.

Temperature There is a certain amount of variation seen in the temperature chart in psittacosis, and in a mild case of the disease it may rise gradually in steplike fashion, to attain a maximum about the end of the first week, and thereafter decline to normal In severe cases it usually tends to be high from the beginning, and may reach 103° or 104° F, and persist at that level with minor fluctuations for several days until death occurs

In general, it may be said that the appearance of the temperature chart in psittacosis conforms to the high and continuous type, and when recovery occurs it falls gradually by a process of lysis Other temperature charts are to be found in the

mitral, aortic, and tricuspid valves (see Reimann and Hutchinson, 1930, Hutchinson, Rowlands, and Simpson, 1930, Polayes and Lederer, 1932).

Vessels Thrombi have been frequently reported by different observers in the following sites pulmonary artery, right ventricle, the iliac and saphenous veins.

The Spleen

The spleen is slightly enlarged, it is soft in consistency and congested in appearance Microscopically the organ is markedly congested, infiltrated with lymphocytes and large mononuclear cells, and areas of hemorrhage, deposits of hemosiderin, and evidence of erythrophagia are also to be seen. Clumps of elementary bodies appear within [illegible] splenic sinuses (see Siegmund, 1930; [illegible] 1930, Polayes and Lederer, 1932, Ru[illegible]

Other Organs

Lymph glands The mediastinal lymph glands, and in particular those of the peribronchial group, are liable to be enlarged and swollen. On section they may contain minute hemorrhages and show reticulo-endothelial hyperplasia, with large lymphocyte and plasma cell infiltration, and areas of necrosis (see Russell, 1931; and Giese, 1930).

Bone marrow. In Haswell Wilson's (1930) case the femur marrow was practically depleted of polymorphonuclear leukocytes, and there was no evidence of proliferation of the myelocytes.

Muscles. Hemorrhages into the rectus abdominis and gluteal muscles as well as waxy degeneration have been observed (see Hegler, 1930, and Hutchinson, Rowlands, and Simpson, 1930).

Skin. Hemorrhages and ecchymoses into the skin are uncommon in psittacosis, but they have been reported by Ritter (1880) and Gastou (1892), and have also been recorded during life by Horder and Gow (1930).

Suprarenal glands Polayes and Lederer (1932) found that although the organ appeared to be normal when examined macroscopically, yet histological examination revealed the presence of congestion, lymphocytic infiltration, and parenchymatous degeneration of the medulla (Peterson, Spalding, and Wildman, 1930).

Kidneys There is congestion of the organ together with varying degrees of degenerative change involving the parenchyma

Esophagus, stomach, and *intestines* are often congested in appearance and minute hemorrhages have been described in their substance, together with infiltration by plasma cells and large mononuclear leukocytes The lymphoid follicles and Peyer's patches are occasionally enlarged slightly (see Polayes and Lederer, 1932, Hutchinson, Rowlands, and Simpson, 1930, Oberndorfer, 1930, Gunther, 1930)

Meninges, brain, and *spinal cord* Congestion of the meninges and infiltration with macrophage cells occurs In the brain, the tissue is hyperemic and multiple punctate hemorrhages appear around blood vessels in the *region of the* corpus callosum, putamen, internal capsule, thalamus, mesencephalon, aqueduct, and the floor of the 4th ventric[illegible]
ing in the claustrum, [illegible]
bellum and cerebrum [illegible]
Rowlands, and Simps[illegible]
1930, Hegler, 1930)

Sprunt and Berry (1936) have described the pathological appearances in a fatal case of psittacosis in a man aged 31 years. In the brain they found no evidence of swelling of neurons, neuronophagia, tigrolysis, or proliferation of glial cells, but there was slight increase in the amount of fat normally present in the ganglion cells Petechial hemorrhages occurred round the smaller blood vessels, and there were no indications of swelling, or degenerative or proliferative changes in the

vestigated by Peterson *et al* (1930) and also by Lillie (1933), who made an histological study of a number of different specimens derived from fatal cases of the disease. From his observations it was found that, although an affected lung might appear to be uniformly consolidated throughout when examined by the naked eye, the consolidation was really lobular in character and not evenly distributed throughout the tissue Thus, histological sections revealed that groups of either serum- or air-containing alveoli still remained in grossly consolidated portions of lung substance Another remarkable feature of the condition was the variability exhibited in the character of the cellular contents present in different alveoli Some of these were filled with serum, while others in addition to serum contained red cells, leukocytes, alveolar epithelium, and macrophage cells, present either individually or collectively with or without the existence of fibrin Lymphocytes and plasma cells also entered into the picture, but polymorphonuclear leukocytes appeared to be localized in the lumina of terminal bronchioles and atria. Many of the cells found in the exudate showed fatty degeneration, the alveolar epithelium and septa were edematous, and infiltrated with lymphocytes, macrophages, and a small number of polymorphonuclear leukocytes

The epithelium of the bronchial mucosa was almost completely desquamated, the medial coat of arteries became thickened, and capillaries were plugged with hyaline thrombi (Wilson, 1930, Polayes and Lederer, 1932; Mansens, 1934).

The pharynx, larynx, and trachea.

Polayes and Lederer (1932) have described the state of these organs in an autopsy performed by them Seen by the naked eye there was submucous edema and swelling of the larynx, trachea, and bronchi, together with hemorrhages beneath the surface of the epiglottis *Microscopically* the exudate in these regions consisted of mononuclear cells, plasma cells, neutrophil leukocytes and areas of extravasated blood The alveolar lining epithelium was desquamated, the cells were swollen, their nuclei enlarged, and numerous large mononuclear cells occurred In thin sections stained by Giemsa's method, clumps of minute purple-staining elementary bodies appeared as intracytoplasmic basophilic inclusion bodies within the alveolar cells, and Lillie (1933), who refers to them as *Rickettsia psittaci*, states that their demonstration can be facilitated in stained preparations by fixing the material in Mallory's permanganate oxalic acid fixative, instead of in formalin or Orth's solution

The Liver

This may be unaffected but sometimes it is slightly enlarged, congested, and areas of fatty degeneration are found on naked-eye examination *Microscopically*, sections show edema and swelling of liver cells with zones of paracentral and centrolobular focal necrosis The outline of the affected cells becomes shrunken, the nuclei are fragmented, their staining reaction tends to be oxyphilic in character, and tiny droplets of fat make their appearance inside the cytoplasm The intervening capillary spaces are filled with polymorphonuclear leukocytes, and sometimes hyaline thrombi The Kupffer cells are swollen, they contain phagocytosed erythrocytes, and more rarely LCL bodies are to be found within their cytoplasm

For detailed descriptions concerning the changes found in the liver in psittacosis the reader is referred to the publications of Siegmund (*1930*), *Sutherland*, *Dunn*, and Maitland (1930), and Lillie (1933)

The Cardiovascular System

Heart The principal changes produced in the heart are dilatation of the right side, hypertrophy of muscle, cloudy swelling of the myocardium, infiltration of the muscle with plasma cells, and subendocardial hemorrhages in the region of the

CHAPTER LXXI

THE VIRUS OF PSITTACOSIS

MORPHOLOGICAL FEATURES

Filtrability and Size

THE VIRUS is not easy to filter through the common types of filter, and there is usually considerable loss of infectivity. It may traverse the following: Seitz EK, Chamberland L_1 bis and L_2, Berkefeld V and N, and Reichel D (Armstrong, McCoy, and Branham, 1930, Bedson, 1930, Elkeles, 1930 *a*, Gordon, 1930 *a*, *b*, Krumwiede, McGrath, and Oldenbusch, 1930, Levinthal, 1930 *b*, Pesch, 1930; Lazarus and Meyer, 1939 *b*).

Direct ... urements have placed the diameter of the coc ... the bacillary forms ranging up to 1000 mμ o ... arus Edlie ...

Electron ...

... 300 mμ ..., and Meyer, 1937, Lazarus and Meyer, 1939 *b*).

Developmental Cycle of the Virus

Bedson and Bland (1932) found that if a mouse was inoculated with a massive dose of virus, the different stages of growth could be observed at will by examination of the spleen at definite intervals In order to demonstrate the virus bodies thin films were made on slides and stained by either the Giemsa or Castañeda method

Fifteen hours after intraperitoneal inoculation of a mouse with a suspension of elementary bodies, the first visible phase of development was the formation of a *plaque* or *plasmodium* inside the cell, which appeared as a light blue or purple-colored homogeneous staining mass.

Twenty-four hours after infection smaller masses developed within the plaques, so that gradually the inclusion body commenced to acquire structural detail, and was now named the *morula* phase of growth As time progressed, distinct elementary bodies began to appear, so that after another 24 hours not only morula phases but also inclusions intermediate between this stage and clumps of elementary bodies were present

At the end of 48 to 72 hours the majority of inclusion bodies had reached the elementary body stage, after which the cell broke down and the virus particles were liberated into the surrounding tissues

Free-lying extracellular virus bodies were usually visible at the end of 24 hours, and these consisted either of fragmented plaques, morulae, or fully developed elementary bodies Elementary bodies were comparatively uniform in size and measured about 0.25 μ in diameter, staining deep pink in color with Giemsa's solution Plaques, however, showed considerable variation in their shape, dimensions, and staining reactions, they measured 1 μ or more in size, showed diplococcal formation, and appeared as diffusely stained structures when seen under the ... scope (see Levinthal, 1930 *b*, 1935 Coles ...

Two theories were originally ... (1933 *a*) in order to interpret the ... by them According to the first o... of the psittacosis elementary bod...

capillary endothelium. Hemorrhages were confined to the Virchow-Robin space, and large phagocyte cells containing fat and hemosiderin appeared in the sites of old hemorrhages. Sprunt and Berry referred to these latter as cerebral purpura, and maintained that the lesions were caused by a toxic change which was secondary to the presence of pneumonia. These same workers also considered that the demyelination reported by Freeman (1933) and Peterson *et al.* (1930) was due to extensive perivascular hemorrhage, and not in the same category as demyelination evident in postvaccinal encephalitis.

Polayes and Lederer (1932) have given a good account of the postmortem findings in the spinal cord in a fatal case of psittacosis which they studied The dura and pia were congested, and on transverse section the posterior cord showed yellowish discoloration. Celloidin and paraffin sections were prepared, and histologically there were p [illegible] anterior horn cells, alteration of the r [illegible] unded and distorted forms possessing [illegible] poorly, and areas of perivascular infiltration and congestion of the blood vessels Hemorrhages occurred into the anterior horn cells and in preparations stained by sudan III small droplets of fat were detected inside the neurons.

LABORATORY DIAGNOSIS OF HUMAN PSITTACOSIS

This is established by inoculating sputum in mice (Rivers and Berry, 1935, Bedson, 1937 *b*), or other animals, or in yolk sacs Lung puncture can be used to obtain material (Yeatman and McEwin, 1945). Tornack (1941 *a*) describes the examination of sputum for EB's using fluorescent microscopy. Advantage may be taken of the bacteriostatic properties of sulfadiazine and streptomycin, which can be added to preparations of sputum prior to inoculation (see Morgan and Wiseman, 1946 *a*).

Failing recovery of virus, acute and convalescent phase sera should be examined by the CFT, more fully discussed below.

This was proved by comparing the relative virulence of 2 types of virus suspension, the one consisting of an emulsion obtained from mouse spleen 48 hours after infection, which consisted mainly of elementary bodies, and the other a similar preparation made 16 hours after infection in which the larger forms of the virus preponderated The results showed that when normal mice were injected with each of these suspensions, death occurred more rapidly in the case of the animals which had received the elementary body suspension than those receiving the emulsion consisting of the large forms. Bedson and Bland point out that "this lower virulence [illegible] normal or [illegible] multipli- [illegible] lty which [illegible] ssential to their growth."

Some Sites in Which Inclusion and Elementary Bodies Occur

Acording to the investigations of Lillie (1930), psittacosis virus is primarily-an-epithelial parasite which is usually found in the microphage and reticulo-endothelial series of cell In man, the inclusion bodies are most evident in the epithelial lining of pulmonary alveoli and also in the periportal connective tissues In the liver they occur inside the Kupffer cells, and in the spleen within the splenic sinuses and macrophage cells of the organ (see Russell, 1931, and Armstrong, 1930) In the case of the parrot, Lillie (1933) reported the presence of elementary bodies within the epithelial cells of the small intestine, ureter, renal secreting tubules, and the bile ducts Inclusions were also found within the epithelioid, macrophage, reticulo-endothelial, and mesothelial cells of these birds In parakeets they were present in the epithelial cells of the renal collecting tubules (see also Rivers, Berry, and Sprunt, 1931). According to Hoge (1934*a*), elementary and inclusion bodies were more numerous in the tissues of the pocket gopher than in any other species of animal susceptible to psittacosis

Inclusions are particularly well seen in the endothelial cells lining the yolk sac It has been found that ether-treatment causes disappearance of the large forms of inclusion, leaving the EB's intact (Kurotchkin *et al*, 1947). Inclusions are also found after amniotic injection, in the tracheal exudate, and superficial epithelial cells of the larger bronchi (Burnet and Foley, 1941) Inclusions have been demonstrated in tissue culture (see above)

TISSUE CULTIVATION

The virus was grown by Bedson and Canti (1935) in their study of the life cycle of the virus (see above). Haagen and Crodel (1937) used the Maitland technique The virus will grow in Li and Rivers' medium, and on Zinsser's solid medium (Yamamura and Meyer, 1941), as well as in roller tube tissue cultures (Morgan and Wiseman, 1946 *b*)

In a series of interesting experiments MacCallum (1936) proved that the presence of living cells was essential for the multiplication of psittacosis virus. Thus, it was shown that the virus failed to grow in cell-free media consisting of chick embryo extract, and even the diffusible growth products of a living tissue culture failed to induce proliferation of the virus in a medium free from cells For the latter experiments, MacCallum employed a principle similar to that adopted in the past by Muckenfuss and Rivers (1930) and Muckenfuss (1931), who devised the method for their investigation into the cultural requirements of vaccinia virus

GROWTH IN THE EGG

The virus grows on the chorio-allantois (Burnet, 1933, Burnet and Rountree, 1935), and multiplies in the ectoderm There is no loss of infectivity for mice on

nass or *plasmodium.* This structure later divided turn subsequently redivided to produce elementary the parasite were structureless in their appearance, Bedson and Bland (1932) considered that at the commencement of its growth the behavior of the virus resembled that of a protozoal parasite rather than that of a bacterium. Subsequent researches by Bedson and Bland (1934) proved this view to be untenable, for it was shown that, although the initial plaques appeared to be homogeneous in structure, they were in reality composed of smaller particles

The true structure of these seemingly homogeneous forms was demonstrated by several different procedures, such as, for example, examining fresh material by darkground illumination, the application of supra-vital staining with brilliant cresyl blue, or the prolonged differentiation of Giemsa-stained preparations with alcohol

In consequence of these later findings, Bedson and Bland (1934) have rescinded their original verdict and offered a second explanation, in which they have maintained that the virus of psittacosis is a micro-organism exhibiting bacterial affinities and not protozoal characters, as was prevously believed

Levinthal (1935) does not agree with Bedson and Bland that the large forms of the virus represent an initial growth phase. He maintains, on the contrary, that when the virus enters a healthy cell the cell resists the invader, and in so doing causes the virus particles to swell up and form a composite deeply staining mass which is devoid of any structure. When the resistance of the cell has been overcome, division and multiplication of the virus then proceed rapidly so that eventually the whole cell becomes packed with elementary bodies Should, on the other hand, the virus enter a damaged cell which is unable to react against it, a prompt and unchecked division of the virus takes place, so that from the beginning of its growth the colony is composed of minute elements No initial large plaque stage of growth would, therefore, be seen if the virus were to enter and develop in a damaged cell

Levinthal also refers to certain forms of the virus, such as rings, disks, and barrel-shaped rods with bipolar staining which resemble thick pasteurella-like organisms, as being degenerate involuted forms of the virus

Bland and Canti (1935) grew the virus in tissue cultures of either fibroblasts or epithelial elements of 9–12 day chick embryos The development of the virus was studied by making stained preparations, as well as by means of the cinephotomicrograph

1 In the early stages, no intracellular inclusions could be seen, but there were numerous EB's

2 From 8–24 hours after infection, round or ovoid intracellular masses were seen, measuring 5–10 μ These bodies were shown to be composed of a mass of bodies 1 μ or less in diameter

3 18–24 hours after infection large masses appeared within the plaques

4 After from 24–48 hours particles varying down to EB's in size developed After 48 hours numerous EB's were seen

5 Between 48 and 72 hours, EB's became the predominant structures They drew attention to a membrane, most readily seen by darkground illumination, encapsulating the colonies In the early stages, the capsule is thick, but gets thinner later This capsule was also noted by Meyer, Eddie, and Foster (1935) in infected sparrows, and somewhat resembles that found in molluscum bodies (van Rooyen, 1938)

Similar developmental forms occur in the infected yolk sac

Observations on the Comparative Pathogenicity of Large and Small Growth Phases of the Virus

Bedson (1933 a) and Bedson and Bland (1934) have drawn attention to the fact that the large forms of the virus are less infective to mice than the smaller varieties

fact that whereas lung changes are the predominant feature of human psittacosis they are relatively uncommon in the parrot (see Heymann, 1930).

Microscopically, the Kupffer cells of the *liver* are filled with hemosiderin and their cytoplasm may contain large basophilic inclusion bodies or numerous elementary bodies, also the bile ducts are damaged and the liver cells necrosed. The *spleen* is infiltrated with lymphocytes and its pigment content is greatly increased. The *kidney* shows focal areas of lymphocytic infiltration and desquamation of tubular epithelium

Lungs. As mentioned earlier, the lungs show comparatively few changes, and this applies not only to parrots which have been spontaneously affected but also to those which have been experimentally inoculated (see Rivers and Berry, 1931, and Lillie, 1930, 1933). In the case of parrots which have been experimentally infected by intramuscular injection of virus into the pectoral region, degeneration and necrosis at the site of inoculation have been described by Levinthal (1930 *a*)

For further details regarding the morbid anatomical and histological features of psittacosis in birds of the species *Amazona amazonica* and *A farinosa* the reader, is referred to the work of Meyer (1931).

Other Birds

Chickens have been experimentally infected by Bedson (1930) who stated that 5 to 9 days after inoculation the animals showed signs of ill health

The *Japanese rice bird* was proved to be susceptible by Levinthal (1930 *b*) who employed it for diagnostic purposes Meyer and Eddie (1933 *b*) likewise obtained positive results with the same bird The *canary* is also receptive to the virus (see Elkeles, 1930 *b*, and Levinthal, 1930 *b*).

The *budgerigar* was found to develop the disease by Bedson (1930), who reported that this species was more resistant than the parrot. Tornack (1941 *b*) discusses the laboratory diagnosis of infection in these birds

Mice

The extreme susceptibility of this experimental animal to parrot strains of psittacosis virus was originally stressed by Gordon (1930 *a*), who in his publication stated that "the outstanding feature of the experiments reported in this paper is the manner in which the strains of virus obtained from parrots associated with the second case of psittacosis have maintained and even increased their virulence by passage through mice" On the other hand, strains of virus isolated from human beings did not appear to be highly pathogenic for mice, and referring to this point Gordon remarks that "the virus derived from human cases has not so far displayed the same degree of pathogenicity, capacity, or stability for mice as that derived from parrots" A similar observation regarding the latter feature was made by Krumwiede *et al* (1930) and Bedson (1930), who found that inoculation of human material into mice did not always produce a fatal illness Bedson showed, however, that the virulence of human strains of psittacosis virus could be exalted in pathogenicity towards mice by first passing the material through birds such as hens, parakeets, or parrots Rivers and Berry (1931 *a*) confirmed these findings.

Following intraperitoneal injection, mice usually die in 6–10 days, but death may be delayed for 3–4 weeks (Bedson, 1930) Mice may appear well, yet be latently infected (Meyer and Eddie, 1933 *b*) Peritonitis is found at autopsy, the spleen is enlarged and shows necrosis and cellular infiltration Inclusions are found in macrophages in the spleen, in the peritoneal exudate, pericardium and pericardial exudate (Levinthal, 1935)

Mice can also be injected intravenously. The cerebral route is effective (Gordon, 1930 *a*, Rivers and Berry, 1931 *a*), and the animals die of meningo-encephalitis in 3–10 days

prolonged passage. Lazarus and Meyer (1939 *a*) reported death of the embryo between the 3rd and 4th day.

It also grows in the amniotic cavity (Burnet and Foley, 1941), and allantoic cavity (Williams, 1944, Francis and Gordon, 1945; Labzoffsky, 1946). The yolk sac is, however, the optimum site for inoculation in the egg when abundant virus is required.

RESISTANCE OF VIRUS TO PHYSICAL AND CHEMICAL AGENTS

Heat. Exposure of the virus for 30 minutes at 55° C. partly destroys but does not completely inactivate it (Gordon, 1930 *a*). Heating to higher temperatures rapidly kills, e.g, 30 minutes at 80° C (see Gordon, 1930 *a*, and Bedson, 1930).

Cold. The pathogenicity of infective material is not altered by freezing the tissues until they turn solid. Bedson (1930) reported that the virus could be preserved in this manner for a period of 10 days.

Desiccation. The virus resists drying and may be preserved for a number of days by subjecting infected mouse spleen to desiccation *in vacuo* over sulfuric acid (Gordon, 1930 *a*).

Centrifugalization at 5,000 r.p m. for 2 hours has been shown to deposit the virus (Bedson and Western, 1930), a further indication of its large size (see also Levinthal, 1935).

Glycerol Bedson (1930) has found that the pathogenicity of infective tissues can be conserved by placing the material in a solution of 50 per cent. glycerol made up in M/50 phosphate solution of pH 7.6. The material was placed in the refrigerator at 34° F., and was found to retain its potency for 20 to 40 days.

Phenol. The virus resists 0 5 per cent. phenol for 20 hours at 37° C, but in connection with tests with phenol, Gordon (1930 *a*) has emphasized the necessity for caution in the interpretation of results owing to the toxicity of 0 5 per cent. phenol solution *per se* to mice.

Ether. The virus was not affected by the addition of 5 per cent. ether to tissues containing it, but the use of 10 per cent. ether caused considerable attenuation in virulence (Gordon, 1930 *a*).

Potassium permanganate. Gordon (1930 *a*) found that a 1 in 10,000 dilution of this substance had no effect on the virus when allowed to act for 30 minutes at room temperature

Other agents The virus is insusceptible to the virus inactivating agent, saponin, sodium desoxycholate, or sodium lauryl sulfate (Burnet, Lush, and Jackson, 1939, Burnet and Lush, 1940) Aerosolized virus is reduced in infectivity by exposure to a cloud of triethylene glycol (Rosebury *et al*, 1947 *b*).

PATHOGENICITY TO ANIMALS

Parrots

Parrots which have not previously suffered from an attack of psittacosis are susceptible to experimental inoculation with virus, when administered either orally, parenterally, or via the respiratory tract

The incubation period varies considerably and ranges from a few days to several weeks, and the principal signs of illness are loss of appetite, diarrhea, disinclination to move, watering of the eyes and nose, with fits of shivering, dyspnea, and convulsions The coat becomes ruffled, the feathers molt, and the bird rapidly loses weight and dies (see Embden and Adamy, 1930) At autopsy, *naked-eye* there are present congestion of abdominal organs, hemorrhages into the myocardium and peritoneum, enlargement with softening of the spleen, miliary nodules in the liver, and fluid in the duodenum with congestion of the pleural cavities Swelling and distension of the upper gut has been described by Bedson (1930) In long-standing cases small foci of consolidation may appear in the lungs, but it is a noteworthy

sided without vesiculation or traces of scar formation (see also Rivers, Berry, and Rhoads, 1930).

Other Rodents

Attempts to infect the wild rat (*Rattus norvegicus*) have been unsuccessful. Likewise similar results were obtained with the Southern California ground squirrel, *Citellus beecheyi beecheyi* Richardson (see Hoge, 1934 *a*).

Some strains are infective for white rats, and the nasal route is more effective than the peritoneal (Chialvo and Parodi, 1944). Cotton rats and hamsters can be infected.

Monkeys

Rivers and Berry (1931 *c*) reproduced lung lesions resembling those found in human psittacosis, by inoculating *Macacus rhesus* monkeys either intratracheally or intranasally with the virus If inoculated by the intracerebral route then meningo-encephalitis accompanied by a mononuclear cell infiltration of the meninges resulted

IMMUNITY

Antigen-Antibody Reactions

Complement fixation has been most studied, and has been widely used in the diagnosis of human and avian infections Bedson (1936) showed that complement fixation is due partly to EB's and partly
terial, there are 2 antigens, one resistant
corresponding antibodies Bedson (1937 *a*
tissue as antigen (see also Meyer and Eddie, 1939 *a*) More recently other antigens have been used tissue cultures (Meyer, Eddie, and Yanamura, 1939, Meyer and Eddie, 1939 *a*), allantoic fluid (Williams, 1944); antigen prepared from the yolk sac by formalin, ether, and centrifugation (Smadel, Wertman, and Reagan, 1943)

Virus neutralizing antibodies develop irregularly, and test mixtures should be injected in mice peritoneally rather than nasally (Rudd and Burnet, 1941).

Opsonization of virus has been shown (Meyer, 1941 *a*).

Agglutination of EB's can be shown, and heat-stable and heat-labile antigens can be demonstrated (Bedson, 1932, 1933 *b*, Lazarus and Meyer, 1939 *c*, Labzoffsky, 1946)

A heat-stable *precipitin* and *allergen* is present in the supernatant fluid remaining after heating a suspension of virus (Bedson, 1936)

Active Immunity on Recovery from Infection

Animals that recover from infection are resistant to a second inoculation In many such cases, the immunity is associated with the continued presence of the virus in the body of the animal (see Meyer and Eddie, 1933 *b*) Certain animals, e g, guinea-pigs, can be hyperimmunized by repeated injections of live virus by a route that does not cause a fatal infection (Bedson, 1933 *b*)

In *man*, second attacks are unusual, but have been reported (Wenckebach, 1936) It is probable that persons frequently exposed to infection become subclinically infected, carry the virus, and become resistant to further attack (see, e g, Gerlach, 1936 *b*)

Active Immunity by Vaccination

Animals, especially mice, can be partially immunized by repeated injections of killed virus The following preparations have been used formolized virus (Bedson, 1933 *b*, 1938), virus inactivated by methylene blue (Levinthal, 1935), formolized tissue cultures (Morgan and Wiseman, 1946 *b*), etherized yolk preparations, egg fluids, and embryo tissue (Wagner *et al*, 1946) It has been found that the peritoneal route is more effective than the subcutaneous Resistance to peritoneal chal-

On nasal inoculation, they develop pneumonia, with EB's in the alveolar and bronchial lining cells, titrations can be performed by counting the focal lesions (Hornus, 1940); Rudd and Burnet, 1941).

Pocket Gopher

The pocket gopher or *Thomomys bottae bottae* is reported by Hoge (1934 *a*) to be more susceptible than the white mouse.

The animals can be infected by any route of experimental inoculation and the pathological lesions produced are constant in character. A subcutaneous dose of 0 2 c c. of a 1 per cent. suspension of virulent mouse spleen which is uniformly lethal to mice in 7 to 8 days usually kills gophers after 3 to 5 days' time. The virus may be serially passaged through these animals, and their tissues are infective to mice. Repeated passage in gophers is said to reduce temporarily the killing time for mice, but this may be restored by successive passage through mice.

At autopsy there is extensive hemorrhagic infiltration of the abdominal wall and peritoneum (following inoculation by any route of administration), enlargement of the liver, and softening of the spleen Microscopically, areas of coagulative necrosis occur in the liver, the cells are oxyphilic in character, their nuclei show karyolysis and karyorrhexis, and there is swelling of the Kupffer cells. The spleen shows areas of caseation and thrombosis, the lungs are hemorrhagic and edematous, and the heart muscle and the kidneys show evidence of cloudy swelling. Impression preparations made from the liver and spleen, when stained by Romanowsky methods, reveal the presence of innumerable LCL bodies, greatly exceeding in number those found in similar preparations made from mice Lillie and Hoge (1934) remark that they can find no evidence to suggest that gophers suffer from psittacosis under natural conditions

Rabbits

Rabbits are susceptible to infection by intracerebral inoculation, and the lesions produced in the central nervous system of these animals have been described by Gordon (1930 *a*) A strain of psittacosis virus which had been isolated from a sick parrot and passaged in mice was inoculated into the brain of a rabbit, and 4 to 7 days later the animal developed signs of meningitis and died At autopsy no organisms could be cultivated from the meninges of the animal. Microscopically, there were seen lymphocytic infiltration and thickening of the meninges, with areas of perivascular "cuffing" surrounding the vessels of the white matter of the brain. Small foci of inflammatory reaction were scattered throughout the organ and there was pronounced degeneration of nerve cells A certain proportion of rabbits inoculated intracerebrally tend to recover from the infection, and unless the virus is passaged within the first week after inoculation it may be lost Rivers and Berry (1931 *b*) found that 4 to 5 days after injection the temperature of the rabbit rose to 104° F. or more, after which it returned to normal by the end of the second week, thereafter the animal recovered completely and became immune to re-infection.

Guinea-pigs

Guinea-pigs were also injected intracerebrally and shown to develop signs of meningo-encephalitis Rivers and Berry (1931 *b*) found that passage of psittacosis virus through guinea-pigs or rabbits did not diminish its pathogenicity for parrots or mice Bedson (1930) found that if guinea-pigs were inoculated intraperitoneally with virulent material they harbored the virus for a short time, and it could be recovered from their tissues by inoculation of mice Injection of psittacosis virus into the pad of the guinea-pig's foot resulted in the formation of redness and swelling which attained a maximum about the 3rd or 4th day, and thereafter sub-

Faroe
moner
petrels
–Sept.
16th, and the human cases occurred between the 30th and 25th of these months (Rasmussen, 1938 *a*, *b*, see *Brit. med. J.*, 1939, *1*, 735) Virus was isolated from the birds by Haagen and Mauer (1938). Since then, numerous cases have been reported, chiefly following exposure to pigeons, less commonly to doves, or chickens (Meyer, 1941 *b*, Alicandri, 1942, Meyer and Eddie, 1942, Meyer, Eddie, and Yanamura, 1942 *a*, Levinson, Gibbs, and Beardwood, 1944, Melamed and Fine, 1944; Meiklejohn, Beck, and Eaton, 1944, Eaton, 1945, Cohen, Gray, and London, 1946).

Infection in pigeons is widespread and has been demonstrated in birds caught in America, Canada, England, S. Africa, and elsewhere (see e g, Coles, 1940, Andrewes and Mills, 1943, Levinson, Gibbs, and Beardwood, 1944, Labzoffsky, 1947). The diagnosis is made by CF tests or isolation of virus

Turkeys, ducks, and chickens have also been found infected, but not wild fowl (Eddie and Francis, 1942).

Infection in pigeons may be acquired in the nest or shortly afterwards. The birds develop a latent infection, and become sick if subjected to overcrowding and other adverse conditions (Meyer, Eddie, and Yanamura, 1942 *a*). The virus, although in general very similar to psittacosis, can be distinguished from it. It infects mice only cerebrally or nasally, and not regularly peritoneally or subcutaneously (Pinkerton and Swank, 1940, Meyer, Eddie, and Yanamura, 1942 *a*). It also infects ferrets, cotton rats, and hamsters nasally, guinea-pigs and monkeys develop focal

toic cavity

The virus is sensitive to penicillin *in vivo* (Heilman and Herrell, 1944 *a*, Turgasen, 1944) The relationship of the virus to other members of the pneumonitis group is discussed in Ch. LXVII.

THE SÃO PAULO PARROT DISEASE

The São Paulo parrot disease was discovered by Pacheco and Bier (1930) and Meyer (1930) during the course of their investigations into an outbreak of psittacosis which affected an aviary at Agua Branca in the State of São Paulo in 1930. The viruses responsible for these two conditions have been compared as follows by Pacheco (1932)

The Virus of Psittacosis	The Virus of São Paulo
Is infective to man, monkey, mouse, rabbit, hen, and canary	Is only pathogenic to psittacidae of the genus *Amazona*
Exhibits neurotropic affinities	Is viscerotropic in character
Forms basophilic intracytoplasmic inclusion bodies	Forms acidophilic intranuclear inclusions (see Rivers and Schwentker, 1932)
Is not destroyed by dessication	Is killed by drying
Duration of illness is 4 to 5 days	Duration of illness is 2 to 8 days
The principal naked-eye pathological lesions are congestion of the intestines and splenomegaly	Areas of focal necrosis are found in the liver, spleen, and lung, congestion of the intestines is sometimes observed
During an attack of the disease the animal shows signs of inactivity and drowsiness accompanied by diarrhea, oculonasal discharge, coughing, and coma before death	Inactivity, loss of appetite, drooping of the wings, whitish or blood-stained diarrhea, and coma are usually present

Both diseases are caused by filtrable viruses which resist glycerol and are not destroyed by heating at 55° C.

lenge is acquired much more easily than resistance to cerebral or nasal challenge (Rudd and Burnet, 1941; Wagner *et al*, 1946).

Although no clinical evidence of illness may follow the challenge, in many cases a latent infection is set up and virus is demonstrable in the tissues (Bedson, 1938, Yanamura and Meyer, 1942).

Although most experiments have been performed with mice, birds such as parakeets and rice birds can also be immunized (Meyer, Eddie, and Yanamura, 1942 *b*).

In *man*, Rivers and Schwentker (1934) inoculated volunteers intramuscularly with suspensions of live virus. There were no ill effects, and antibodies developed.

Serum Antibodies

Antibodies develop in animals naturally or experimentally infected. In man the complement fixing antibody has been most studied, as virus neutralizing antibody is difficult to demonstrate (Rivers and Berry, 1931 *a*; Bedson, 1933 *b*). The complement fixation test, using antigens already described, may first become positive as early as the 8th to 12th day of illness, but may appear later, a definite rise in titer should, of course, be demonstrated between acute and convalescent phase sera (Pye-Smith, Guest, and Bedson, 1933; Bedson, 1935; Fortner, 1936, Meyer, 1940, Sordelli and Savino, 1940, Favour, 1943).

It must be realized that a positive reaction in the CFT only indicates infection by a member of the LGI-psittacosis-pneumonitis group (see Ch LXVII)

Passive Immunity

Convalescent serum has been recommended for trial in cases of human infection (Meyer and Eddie, 1939 *a*).

ACTION OF CHEMOTHERAPEUTIC AGENTS AND ANTIBIOTICS

Chemotherapeutic and antibiotic agents have been shown to have some effect against psittacosis virus. Thus, *sulfadiazine* given in the diet saves mice from death, but they become carriers (Early and Morgan, 1946 *b*). The drug has a marked inhibitory effect on the growth of some strains of virus in eggs (Early and Morgan, 1946 *a*; Meiklejohn, Wagner, and Beveridge, 1946).

PABA given in the diet did not save mice (Early and Morgan, 1946 *b*), nor was it effective in eggs (Early and Morgan, 1946 *a*)

Large doses of *penicillin* subcutaneously save the majority of mice from death, but they usually develop a symptomless infection, and become resistant to reinoculation (Heilman and Herrell, 1944 *b*, Bedson and May, 1945, Early and Morgan, 1946 *b*). Penicillin inhibits virus growth in tissue culture, but is not so effective in eggs (Early and Morgan, 1946 *a*, Meiklejohn, Wagner, and Beveridge, 1946)

Streptomycin has not been found effective in mice (Early and Morgan, 1946 *b*), tissue cultures or eggs (Early and Morgan, 1946 *a*).

Some human cases of psittacosis appear not to have been benefited by sulfonamides (see e g, Toomey and Lohrey, 1946), but others have improved with penicillin and sulfonamides (Rosebury *et al*, 1947 *a*).

INTRANUCLEAR INCLUSION VIRUS

This virus causes intranuclear inclusions of the herpetic type in pigeons There are focal necrotic lesions in the viscera The virus is smaller than psittacosis, and immunologically distinct Pigeons may be infected simultaneously with psittacosis and INI virus (Smadel, Wall, and Gregg, 1943, Smadel, Jackson, and Herman, 1945).

ORNITHOSIS

This term is applied to a closely related infection contracted from sea birds, pigeons, doves, and similar birds.

CHAPTER LXXII

LYMPHOGRANULOMA INGUINALE (CLIMATIC BUBO)

LYMPHOGRANULOMA INGUINALE (LGI) is the term most commonly used in Britain to describe a disease previously known variously as climatic bubo, venereal bubo, poradenitis, malady of Durand, Nicolas, and Favre, 4th venereal disease, or 6th venereal disease The condition is also known as lymphogranuloma venereum and lymphopathia venerea It should on no account be confused with either granuloma inguinale or lymphadenoma (Hodgkin's disease).

Lymphogranuloma inguinale is an infective disease, usually spread by venereal contact and manifested by a wide variety of clinical features. It is most frequently seen in warm climates and can be diagnosed by cutaneous and other tests A virus which is transmissible to numerous experimental animals can be isolated from the lesions

Stannus (1933) reviewed over 900 papers, and there has been no lessening of interest since that date A numbe
(Coutts and Bianchi, 1934, Wassé
and von Haam, 1939, Favre and
Grace, 1941 *b*, Hickam, 1945).

CLINICAL FEATURES

For many years a disease of the inguinal lymphatic glands known as climatic bubo was familiar to those practicing in the tropics, and was from time to time recognized elsewhere among persons returned from abroad Infection was known to occur following sexual intercourse, but despite this fact almost all the recognized cases were in males.

For some considerable time a very similar condition was also known to workers in cooler lands such as France, Germany, Italy, and Scandinavia, and was named lymphogranuloma by Durand, Nicolas, and Favre in 1913 (*a*, *b*) because of an histological similarity to lymphadenoma. They did not, however, realize that they were dealing with the disease known in warmer lands as climatic bubo Interest was interrupted by World War I, but revived thereafter when the identity of CB and LGI soon became established. Amongst work which contributed to this view may be mentioned the introduction of Frei's cutireaction in 1925, the transmission of the virus to monkey.
diti *et al* in 1932 (*b*).
infected mice with th
in the tropics He was able to show that infection of mice could be prevented by the serum of cases of LGI obtained from Paris

Earlier Manifestations of LGI

The primary sore Following an incubation period of from 3 days to about 3 weeks, the primary lesion develops, usually in the genital region In males it is commonly on the penis, especially the glans In women while it may be on the labia, it is commoner on the vaginal wall or cervix Primaries may occur in the region of the anus The primary lesion may take one of four forms (Chapman and Hayden, 1937) (1) herpetiform and transient, (2) an ulcer, (3) a nodule, (4) a non-gonococcal urethritis (*see below*). Extragenital primaries may occur on the finger, tongue, or tonsil (Klotz, 1890, Ravaut and Scheikevitch, 1921, Buschke and Curth, 1931; Bloom, 1933, David and Loring, 1936, Tanahashi, 1936).

the aperture. This type of stricture is usually single, but may be multiple, and is not progressive.

2. A funnel-shaped stricture, from 2 to 6 cm. long, with its smallest aperture proximally, may be found, the overlying mucosa is glistening and hyperplastic, while distally it is ulcerated and polypi may be present.

3. This type is found rarely; it occurs where the whole bowel distal to the pelvirectal junction is involved

Clinical features of stricture. In the early stages there is usually a complaint of pruritus and burning in the anal region, the mucosa being swollen and hyperemic (Mathewson). Later, there is bloodstained mucoid discharge, with tenesmus. Constipation and sometimes even acute obstruction may occur. Examination shows the

Michelson *et al.* (1938) recorded a normal delivery in a case of rectal stricture, while Mathewson (1938) has reported that cesarean section may be needed in certain cases Coutts and Monetta (1938) recorded a birth in a case of ulcero-elephantiasis which was normal except for a temporary retention of the placenta.

(*e*) *Involvement of alimentary tract.* Some cases of ulcerative colitis, and perhaps even ileitis, may be due to LGI (Paulson, 1937, 1938, 1939; Whittaker, 1937, Coutts, Opazo, and Montenegro, 1940). Rodaniche, Kirsner, and Palmer (1940), however, did not find evidence of a close association with colitis Coutts

"leather-bottle" stomach.

LGI may cause urethritis, stricture

Polak, 1933, Mauro, 1939, Itikawa and Shinoda, 1939–40, Coutts, 1943 *a*, *b*, Tauber, 1945, Fowler and Walker, 1947). The condition known as Waelsch's "sago-grain" urethritis may in some cases be due to LGI (see Harrison and Worms, 1939, Melczer and Wlassics-Venkei, 1930).

Leukoplakia of the bladder may occur (Carloni, 1944), and chronic cystitis (Coutts and Vargas-Zalazar, 1945).

Epididymitis has been reported (Coutts and Herrera, 1938, Sicard, Leger, and Levaditi, 1945)

Other Manifestations of LGI

It has come to be recognized that LGI is more than a disease localized merely to the pelvic organs, for a variety of other changes may occur (see Coutts, 1936; von Haam and D'Aunoy, 1936 *b*, Chapman and Hayden, 1937, Eberhard, 1938, Jones and Rome, 1938, Gutman, 1939).

1 The throat may be involved, with inflammation of the tonsils, ulceration, or angina Alverson (1941) described a granulomatous condition of the larynx and hypopharynx

2 The patient is often febrile and suffers from headaches and other pyrexial disturbances.

3 Skin rashes have been described (see e g, Hellerstrom, 1929, Lohe and Blummers, 1931, Kleeburg, 1931, Melczer and Sipos, 1938 *b*, Benedek and Olkon, 1941). There seems to be a relationship between LGI and erythema nodosum in some cases (Sonck, 1940 *b*, 1941, Hellerstrom, 1941, Hickam, 1945). Sonck (1940 *a*) refers to the frequency of solar eruptions

4 Various forms of articular affection have been attributed to LGI (Gottlieb, 1932 *b*, Jones and Rome, 1938, Sonck, 1941, Hickam, 1945), e g., arthralgia, polyarthritis, and effusion Osseous changes may occur (Wright and Logan, 1939).

5 There is often generalized enlargement of the lymphatic glands, the liver, and spleen

Lymph gland involvement. The primary lasts for a few days and then the virus spreads by lymphatic vessels to the regional glands, where it causes inflammation and suppuration. The distribution of the pelvic lymphatics in the male and female is of considerable importance in determining the future course of the infection (Barthels and Biberstein, 1931; Nesselrod, 1936 *a*, *b*). In males, the primary lesion being usually on the penis, the inguinal glands are first involved. Suppuration occurs with the formation of large buboes, which may break down to form sinuses. Sometimes, however, the primary may be intra-urethral and infection can then spread from the posterior urethra to the intrapelvic glands (see e g, Mathewson, 1938) If the primary is in the anorectal region, the infection also reaches the pelvic glands (Feilchenfeld, 1932).

Rarely, inguinal buboes may be accompanied by enlargement of glands elsewhere (Costello and Cohen, 1940).

In females, primaries on the external genitalia may give rise to lymph gland involvement in the groin. More usually, however, the primary is intravaginal and infection spreads, posteriorly to intrapelvic glands.

Later Pelvic Manifestations of LGI

The genito-anorectal syndrome. This is the term usually applied to the tertiary stages of LGI and includes a number of disorders attributed to involvement of the lymphatic system and adjacent structures by a chronic inflammatory process. It has been suggested that the syndrome predisposes to malignant change (Coutts, Brieva, and Lerner, 1942).

(*a*) "*Esthiomène.*" The term "esthiomène" is applied to a chronic granulomatous condition of the vulva, which becomes swollen and infiltrated, and fistulae, ulcers, and sinuses may form. The disease is usually associated with other manifestations of infection

(*b*) *Elephantiasis* In certain cases elephantiasis of the vulva without other destructive lesions may occur In the male, elephantiasis of the penis and scrotum has been attributed to LGI (see e g., Stannus, 1933, Stryker and Ploch, 1935). Plastic induration of the penis may be caused by LGI (May, 1944)

(*c*) *Pelvic inflammation* Cases of salpingitis and tubo-ovarian abscess have been attributed to LGI (D'Aunoy and Schenken, 1938, and Franci, 1934, respectively) Kondo (1935) reported that glands might rupture and set up peritonitis

(*d*) *Rectal stricture* The condition of benign rectal stricture has been known to surgeons for many years Formerly attributed to syphilis, traumata, or other causes, it is now recognized that the virus of LGI is the cause of the great majority.

This form of rectal stricture is being increasingly recognized in many parts of the world, and in particular in N America (Frei and Koppel, 1928, Lutz, 1932, Cole, 1933, Bacon, 1935, Lichtenstein, 1936, Chapman and Hayden, 1937, Mathewson, 1938, Peyton, 1940, Grace, 1943, Armstrong and Niebauer, 1944) A few cases contracted in Britain have been recorded (Findlay, 1935–6, Manson-Bahr, 1935–6, Whittaker, 1937).

The lesion is generally thought to be predominantly one of women, especially of the colored races. Certain recent papers, however, have reported the occurrence of strictures in men, and the practice of sodomy accounts for some of these, primary in the anal region giving rise to an intrapelvic spread of virus In other cases an intra-urethral primary has probably been responsible Chapman and Hayden recorded 11 cases in men, and Mathewson no less than 60

Virus may reach the rectum by invasion of the perirectal tissue, or, as suggested by Grace (1941 *b*), by direct implantation of virus on the mucous lining.

Types of stricture. According to Mathewson, who has published one of the most authoritative articles on the subject (74 cases), there are 3 types of stricture·

1. An annular diaphragm of fibrous tissue forms about 1 to 6 cm. above the ano-cutaneous margin. He states that the proximal mucosa may permeate through

the aperture. This type of stricture is usually single, but may be multiple, and is not progressive.

2. A funnel-shaped stricture, from 2 to 6 cm long, with its smallest aperture proximally, may be found, the overlying mucosa is glistening and hyperplastic, while distally it is ulcerated and polypi may be present.

3. This type is found rarely; it occurs where the whole bowel distal to the pelvirectal junction is involved

Clinical features of stricture. In the early stages there is usually a complaint of pruritus and burning in the anal region, the mucosa being swollen and hyperemic (Mathewson). Later, there is bloodstained mucoid discharge, with tenesmus. Constipation and sometimes even acute obstruction may occur. Examination shows the distal mucosa to be papillomatous In the late stages fistulae form and may open into the vagina Often "esthiomène" or elephantiasis is present as well.

Pregnancy and genito-anorectal syndrome. Little has been written about the effect of "esthiomène," rectal stricture, or other manifestation upon pregnancy. Michelson *et al* (1938) recorded a normal delivery in a case of rectal stricture, while Mathewson (1938) has reported that cesarean section may be needed in certain cases. Coutts and Monetta (1938) recorded a birth in a case of ulcero-elephantiasis which was normal except for a temporary retention of the placenta.

(*e*) *Involvement of alimentary tract.* Some cases of ulcerative colitis, and perhaps even ileitis, may be due to LGI (Paulson, 1937, 1938, 1939, Whittaker, 1937; Coutts, Opazo, and Montenegro, 1940). Rodaniche, Kirsner, and Palmer (1940), however, did not find evidence of a close association with colitis Coutts and Brieva (1942) demonstrated inclusions in "leather-bottle" stomach.

(*f*) *Involvement of urethra and bladder.* LGI may cause urethritis, stricture may occur (Anwyl-Davies and King, 1933, Polak, 1933; Mauro, 1939; Itikawa and Shinoda, 1939–40, Coutts, 1943 *a*, *b*, Tauber, 1945, Fowler and Walker, 1947). The condition known as Waelsch's "sago-grain" urethritis may in some cases be due to LGI (see Harrison and Worms, 1939, Melczer and Wlassics-Venkei, 1939).

Leukoplakia of the bladder may occur (Carloni, 1944), and chronic cystitis (Coutts and Vargas-Zalazar, 1945).

Epididymitis has been reported (Coutts and Herrera, 1938, Sicard, Leger, and Levaditi, 1945)

Other Manifestations of LGI

It has come to be recognized that LGI is more than a disease localized merely to the pelvic organs, for a variety of other changes may occur (see Coutts, 1936, von Haam and D'Aunoy, 1936 *b*, Chapman and Hayden, 1937, Eberhard, 1938, Jones and Rome, 1938, Gutman, 1939)

1. The throat may be involved, with inflammation of the tonsils, ulceration, or angina Myerson (1941) described a granulomatous condition of the larynx and hypopharynx

2 The patient is often febrile and suffers from headaches and other pyrexial disturbances

3. Skin rashes have been described (see e g., Hellerstrom, 1929, Lohe and Blümmers, 1931, Kleeburg, 1931, Melczer and Sipos, 1938 *b*, Benedek and Olkon, 1941). There seems to be a relationship between LGI and erythema nodosum in some cases (Sonck, 1940 *b*, 1941, Hellerstrom, 1941, Hickam, 1945). Sonck (1940 *a*) refers to the frequency of solar eruptions

4 Various forms of articular affection have been attributed to LGI (Gottlieb, 1932 *b*, Jones and Rome, 1938, Sonck, 1941; Hickam, 1945); e g, arthralgia, polyarthritis, and effusion Osseous changes may occur (Wright and Logan, 1939).

5 There is often generalized enlargement of the lymphatic glands, the liver, and spleen

6. It is probable that vascular disease may be caused by LGI (Coutts and Davila, 1945; May, 1945; Soriano and Yrastorza, 1945).

7. A few cases of meningo-encephalitis have been reported (Rajam, 1936, Sabin and Aring, 1942, Zarafonetis, 1944, Scott, 1945).

8. Various ocular conditions have been attributed to LGI, e g, iritis, keratitis, keratoconjunctivitis, uveitis, Parinaud's syndrome, chalazion, and pterygium (Levaditi *et al*, 1936 *b*, Ouwejan, 1939, Vasquez-Barrière and May, 1940, Benedek and Olkon, 1941; Macnie, 1941, Espíldora and Coutts, 1942; Scheie, Crandall, and Henle, 1947).

9. Pleurisy and ascites may occur (Litarczek and Chisăr, 1939).

10. LGI may be an etiological factor in certain cases of otosclerosis (Chiarino, 1942; Mourao, 1945).

Infection in Children

A few cases of presumably acquired LGI have been recorded, predominantly in the female child, while inguinal adenopathy is common, rectal changes may also occur (Levy, 1937, Sonck, 1939, 1940 *a*, Levy, 1940, Winge, 1941) Dick (1936) described a case of rectal stenosis that may have been hereditary. The Frei test however is usually negative in the children of Frei-positive mothers (see below)

DISTRIBUTION OF THE VIRUS

The primary lesion. Virus has been found in primary lesions (Lohe *et al*, 1933; Shimoda, 1939)

Pus. The virus is regularly found in the pus from inguinal buboes, and it was with this material that the original transmission experiments of Hellerstrom and Wassén, Levaditi, and Findlay were performed

Tertiary lesions A number of workers has been successful in isolating the virus from the rectal tis[illegible]t *et al*, 1932, Laederich *et* [illegible] Jollaret, and Remié, 1935, [illegible] Caminopetros, 1938 *a*) Lo[illegible] a case of "esthiomène"

It should be noted that Caminopetros (1935) isolated virus from the urethral and cervical tissue of prostitutes known to be spreading the disease, although they did not show any manifestations of infection.

Infection of the epididymis and seminal vesicle, and of the ovaries, has been recorded (see Coutts and Monetta, 1938). Virus has been isolated from ascitic fluid in a case of acute peritonitis developing in the course of LGI (Aoyama, 1938)

Blood Virus was isolated in one case (Beeson, Wall, and Heyman, 1946), Findlay (1933–4) obtained negative results

Cerebrospinal fluid Virus has been found in the cerebrospinal fluid (Coutts *et al*, 1933; von Haam and D'Aunoy, 1936 *a*, Jones and Rome, 1938, Beeson, Wall, and Heyman, 1946)

Feces Paulson (1937, 1938, 1939) has reported that the feces of cases of ulcerative colitis, in patients giving a positive Frei intradermal test, may contain the Frei reacting substance, and thus postulates the presence of the virus in the feces of such cases. He has prepared Frei antigen from the feces and produced a positive reaction on intradermal injection of known cases of LGI (see also Paulson and Kravetz, 1938)

CLINICAL PATHOLOGY

Albuminuria is not uncommon There is a slight "secondary" anemia, leukopenia is found in the early stages, but a polymorph leukocytosis occurs at the suppurative stage (Ishizuka, 1938 *a*, Jones and Rome, 1938). The BSR is increased (Nicolau, 1931, Michelson *et al*, 1938, Ishizuka, 1938 *a*, Schmidt, 1938, Gsell, 1939)

Hyperproteinemia, due to increase of globulin, occurs in LGI and parallels the ata tests are usually positive (Gutman Gutman, 1936, Gutman *et al.*, 1936, 9, Longhin and Stoian-Ionesco, 1937, Michelson *et al*, 1938, Gsell, 1939, and Miller, 1944 *a*, Combes, Cañizares, and Landy, 1945). Although the serum protein rises to 10 per cent or more, there is no associated hypercalcemia (Williams and Gutman, 1936).

The lipoid content of the serum is said to be below normal (Rosen *et al*, 1937, 1939), but Jones and Rome (1937) reported a hypercholesterolemia

PATHOGENESIS

loma inguinale is primarily a disease of the

in the female the pelvic, glands are those most commonly involved.

It appears that tertiary lesions are more prone to develop in those who have not shown buboes

The differing clinical picture in the lymph glands and rectal tissue is explicable by the reactivity of these organs, although adenitis heals in a few weeks, the rectal lesion persists (Caminopetros, 1939)

PATHOLOGY

According to Sheldon and Heyman (1947)

ble for the vascular occlusion

A. Primary Lesion

There is little that is characteristic about the primary ulcer. The surface epithelium is denuded, and the ulcer cavity is surrounded by tissue showing a marked infiltration with small round cells, plasma cells, and perhaps histiocytes (see Bory, 1921, Shinoda, 1939)

B. Lymphatic Glands

The histology of the glands has frequently been described (e g, Phylactos, 1922, Hellerstrom, 1929, Thomson, 1936, Hiraga, 1937, Anderson and Harmos, 1938, Tanahashi, 1938, Sepulveda, 1942)

The glands are matted together by much fibrous and granulation tissue. In the more advanced cases suppuration is present and the glands may be adherent to the overlying skin, with fistula formation On section, the periglandular tissues show an inflammatory reaction more or less acute, and the gland capsule is thickened. The gland substance shows numerous small lesions scattered throughout. In the early stages there is much cellular proliferation with formation of small nests of mononuclear cells. Later these nests become necrotic in the center, polymorphs appear and small abscesses, which eventually coalesce, result. These abscesses are surrounded by

be found

The follicu

material ca

observed In certain cases the glands become fibrotic, and in the dense material occur small abscesses In a case examined post mortem by Reichle and Connor (1935) the entire retroperitoneal chain of glands was involved in the process.

C. Tertiary Lesions

In males, the primary lesion is so situated that the glands affected are the inguinal. In the female, however, owing to the usual site of the primary, the affected glands are intrapelvic. In the male, suppuration occurs and the disease tends to limit itself, tertiary manifestations being rare. In the female, however, the infection spreads in the pelvis and pudenda and may cause two main types of tertiary lesion, often classed together as the genito-anorectal syndrome.

"Esthiomène." This term includes a variety of lesions of the vulva The labia are usually affected, being greatly thickened, nodular, and edematous, ulceration is frequently superimposed and a urethral or rectal fistula may form Condylomata may be found around the urethral or anal orifices Histologically, the changes are of the same nature as those found in the glands. The thickening of the parts is due to newly formed granulation tissue in the dermis, and there is a marked cellular infiltration with lymphocytes, histiocytes, polymorphs, and a number of giant cells. Small abscesses may be found resembling those described in the glands.

Rectal stricture. This is predominantly a disease of women, the ratio being probably 4 or 5 cases in women to every 1 in men. As has already been noted, however, cases in men are not uncommon. The stricture is usually situated a few centimeters above the anus. It is most frequently of the ring type and is often associated with [illegible]
ulceration of th [illegible]
replacement of [illegible]
with lymphocytes, plasma cells, and endothelioid cells (e.g, Barthels and Biberstein, 1931; Lichtenstein, 1936). Small abscesses may also be found. The mucosa is ulcerated, and on regeneration there is a tendency to squamous metaplasia. Falconer (1938) found very similar changes in a case of colitis in a patient who had LGI 15 years before. Lichtenstein reported that the final stage of LGI infection is the condition known to surgical pathologists as "chronic ulcerative stenosing proctitis and periproctitis"

D. Other Changes

Reichle and Connor (1935) found a psoas abscess, venous thrombosis in the adrenals, and a proliferative glomerulitis. Wohlwill (1943) concluded that the virus causes a general activation of the reticulo-endothelial system, in one case he found granulomatous lesions in the spleen

E. Inclusion Bodies

Gamna (1923, 1924) and Favre (1924) described inclusions (Gamna-Favre [illegible] ionuclears, and polynuclears, in lymph [illegible] nd are spherical, cone, or dumb-bell [illegible] be surrounded by a vacuole. Findlay (1933–4) found that they gave a positive Feulgen test, a negative test for fat, and did not stain with Janus green B for mitochondria, thus proving their nuclear origin. The present opinion is that Gamna-Favre bodies are of nuclear or nucleolar origin, some being the remains of phagocytosed lymphocyte nuclei, and others nucleolar extrusions. Whatever their origin, they are certainly of diagnostic value (Todd, 1926).

Miyagawa *et al.* (1935 *a*) have described quite different inclusions which they [illegible] These measure [illegible] They may be [illegible] ves no reaction (see also Robinow and Bland, 1938), the bodies are not stained by Gram's method These granules are found in varying numbers in the cytoplasm of histiocytes, and sometimes lymphocytes and polymorphs of human lymph glands Cells around the

small localized abscesses contain more than do other cells Cells containing these structures show no signs of degeneration unless they are present in very large numbers Similar bodies are also found lying free, often seeming just to have ruptured from a cell. These granules have also been found by Satani and Sano (1936), Mauro (1937); Melczer (1938); Caminopetros (1938 *a*), Coutts and Herrera (1938), Pirilla (1942).

Coutts and his collaborators (Coutts, 1946) have found inclusions in small groups or clusters varying from 0 2–2 μ in size in material from the buccal cavity, vulva,

Fig 38 Fig. 39

Figs. 38 and 39 Inclusions of lymphogranuloma inguinale. Fig 38 shows morula type of inclusion in rectal tissue, Fig 39 shows inclusions in tissue in a case of ptyergium

(By courtesy of Dr W E. Coutts, Santiago, Chile)

vagina, urethra, and rectum Small forms 0.2–0 8 μ are usually found free and in large numbers Larger forms up to 1 μ appear free or in the cytoplasm of histiocytes, singly, in pairs, or clusters Forms resembling Russell bodies, 1–3 μ in diameter are found free or in histiocytes These bodies resemble those described by Ishimitsu (1936, 1937). Although a number of authors has disputed the specificity of the Russell body type of inclusion, Coutts is convinced of their viral nature, and finds them more frequently in tertiary lesions Coutts and his collaborators have found inclusions in lung tissue, blood vessels, stomach, bladder, conjunctiva, lacrimal duct and sac, and gallbladder, in addition to the better-known lesions (see Figs 38 and 39)

EPIDEMIOLOGY

Method and Source of Infection

By far the commonest method of infection is by sexual intercourse. The disease is especially prevalent among colored prostitutes Although many of these suffer from the genito-anorectal syndrome, it appears that in certain cases the disease may be transmitted by one who seems to be free from clinical signs. Further, Caminopetros (1935) isolated the virus from the urethra and cervical canal of such persons, although they showed no evidence of abnormality. Studies of the Frei reaction have shown that in certain areas up to 40 per cent or more of these women may react positively. Thus in St Louis it was found that 47 7 per cent of colored prostitutes reacted positively to this test (Gray *et al*, 1936) In Brazzaville (French Congo) 43 5 per cent gave a positive Frei test (Saleun, Ceccaldi, and Gourvil, 1936) Sorel (1936) in French Equatorial Africa found that 27 out of 68 such persons showed a positive test (for similar reports see Vaucel *et al*, 1936,

Histologically, the brains of infected monkeys show a diffuse leptomeningitis In the acuter cases the leptomeninges are infiltrated with a fibrinous exudate in which are found polymorphs. Perivascular cuffing is a prominent feature. In chronic cases the cellular infiltration is composed more of lymphocytes, plasma cells, and macrophage cells which may show Gamna-Favre bodies or granulocorpuscles.

Hellerström and Wassén were also able to infect monkeys by intrapreputial and intraperitoneal injections. It has been reported that after injection of virus intracerebrally or intraperitoneally pseudotabetic manifestations may develop, with histological changes in Goll's column (Jonesco-Mihaiesti *et al.*, 1932 *a, b*, 1933 *a, b*). On peritoneal injection a cellular exudate may form (Mesrobeanu, 1938, 1939) Findlay (1933–4) carried out injection into the groin. Injection into the wall of the intestine or rectum may secure a positive result (Levaditi and Reinié, 1934, Levaditi, Mollaret, and Reinié, 1935), as may intrapulmonary injection (Caminopetros, 1934). Findlay (see 1935–6) injected the tissues anterior to the rectum. A typical inflammatory reaction developed locally, and the virus was isolated from enlarged inguinal glands.

2. Mice.

The high price of monkeys renders them unsuitable for use in large numbers Fortunately, however, it was discovered by Levaditi *et al* (1932 *b*) and Findlay (1932) that the disease was transmissible to mice by intracerebral injection. These observations have been confirmed by various authors (D'Aunoy and von Haam, 1936 *b*, Mesrobeanu and Bruckner, 1936, Cottini, 1938 *b*, Gavrilof and Fester, 1939) *The infected animals develop a characteristic meningitis in 7 to 14 days as shown* by muscular incoordination, paresis, and weakness. Two strains studied by Findlay (1938) produced symptoms in 2 to 4 days Conjunctivitis may also occur.

The histological appearances are similar to those of the monkey, and granulocorpuscles can be found. Granulocorpuscles are most abundant between the 5th and 20th days, and occur especially in the ependymal cells covering the infundibulum of the 3rd ventricle, and in monocytes in the ventricular exudate (Levaditi, 1944 *a, b, c*), histological changes can be found after 3–4 days (Levaditi, 1944 *c*) Mice sometimes show no clinical evidence of infection following intracranial injection, Levaditi and Schoen (1936) found a hydrocephalus to be present in certain of such animals. Virus may persist for a very prolonged period in the brain in inapparent infections (Levaditi, 1944 *d*, Wall, 1947). Virus can be found in the CSI (Okanishi and Vio, 1937)

Mice may be infected by the intracutaneous and intratesticular routes also. They can be infected intraperitoneally if starch is injected intracerebrally (Findlay, 1933–4)

The virus can be passed by
consolidation occurs in 48–72
in the alveolar lining (Schoen,
and O'Donnell, 1944, Landau
solidated foci visible *in situ;* 1
mum concentration by the 31
mice are infected, *the virus is transmitted to the fetus (Hellendall, 1942, 1945)*

Findlay (1938) has reported that strains of virus may vary considerably in the ease with which they infect mice Thus, of 26 strains transmitted by him to mice only 2 proved highly virulent, while others lost their virulence with passage

3. Guinea-pigs.

Following injections of infective material into the groin, between one-third and one-half of animals develop enlarged inguinal glands This was probably first shown by Gamna (1923, 1924), and it has since been confirmed by other workers (see,

e g, Meyer, Rosenfeld, and Anders, 1931; Freund and Reiss, 1931), most of whom stress the fact that 3 or 4 animals should be injected, in order to secure at least 1 positive result The histological picture shows a marked reticulo-endothelial response. Sections of the infected gland show a great increase in the number of histiocytic cells, many of these containing Gamna-Favre bodies In many cases

[illegible] hocyte nuclei, as consid- [illegible] Guinea-pigs can also be [illegible] gawa *et al.*, 1936 *a*, Grace [illegible] d Sano, 1936, Grace and [illegible] ros, 1934), intratesticular [illegible] perianal region (Caminopetros, 1938 *a*), into the vaginal mucosa, or into the prepuce (Grace and Suskind, 1940).

Some workers have failed to infect using the intracerebral route, but others have produced meningo-encephalitis and found granulocorpuscles (Coutts *et al*, 1939, 1942 *a*).

The nasal and peritoneal routes are not effective (Schoen, 1939 *d*, Grace and Suskind, 1940, Beck, Eaton, and O'Donnell, 1944).

Histological changes have been recorded in the kidneys in infected guinea-pigs (Coutts, Brieva, and Lerner, 1943).

Other animals.

[illegible] the

[illegible] ijections

5. *Cats*, by intracerebral injection (Levaditi *et al*, 1932 *d*, D'Aunoy and von Haam, 1936 *b*), the phenomenon of "autosterilizable neuro-infection" may be noted (Levaditi *et al.*, 1933 *a*).

6. *Rats*, by intratesticular and intracutaneous injections (Miyagawa *et al.*, 1936 *a*) White rats have been infected by the cerebral and nasal routes as have kangaroo rats (Eaton, Martin, and Beck, 1942).

7. *Rabbits* can be infected by various routes intracranially (Freund and Reiss, 1931, Coutts *et al.*, 1939, 1942 *a*), intracutaneously (Miyagawa *et al*, 1936 *a*), by corneal scarification, by anterior chamber injection, and by intratesticular injection (Satani and Sano, 1936, Li, 1940 *a*, Coutts, 1946), by intrapulmonary injection (Caminopetros and Photakis, 1935, von Haam and Hartwell, 1937 *a*), the changes being those of an interstitial pneumonia with proliferation of endothelioid cells, subcutaneously and intraperitoneally (Li, 1940 *a*) Malamos (1937) infected the corneae of 5- to 6-day-old rabbits, granulocorpuscles being found. The nasal route is not effective (Schoen, 1939 *d*).

8 *Voles* (and rabbits) may harbor the virus in their brains after intracerebral injection without any apparent symptoms (Findlay, 1933–4).

9 *Fowls*, by intracutaneous injection (Miyagawa *et al*, 1936 *a*).

10. *Squirrels*, by the intracerebral, intratesticular, and intracutaneous routes (Miyagawa *et al*, 1936 *a*, Satani and Sano, 1936).

11 *Marmots*, by intracerebral injection (Malamos, 1937, Nauck and Malamos, 1937)

12 *Sheep*, by intracerebral injection (D'Aunoy and von Haam, 1936 *b*).

13. *Hamsters* have been infected by the nasal and cerebral routes (Eaton, Martin, and Beck, 1942, Beck, Eaton, and O'Donnell, 1944).

14 *Cotton rats* have been infected nasally (Beck, Eaton, and O'Donnell, 1944)

15 Infection could not be passed in the bat by the cerebral route (Meneghini, 1940)

TOXIC PROPERTIES OF THE VIRUS

A labile toxin, not readily separated from EB's, has been demonstrated in heavily infected yolk sac material. After intravenous or less commonly intraperitoneal injection, mice usually die in 4–24 hours, and show necrotic foci in the liver (Rake and Jones, 1943, 1944). The toxin can be converted to toxoid with formalin (Rake and Jones, 1944).

Antibodies can be produced in rabbits or chickens against the toxoid or toxin (Rake and Jones, 1943, 1944). Toxin may be neutralized by convalescent serum (Shaffer *et al.*, 1944); it is not affected by sulfonamides (Rake and Hamre, 1944).

MORPHOLOGY OF THE VIRUS

Elementary and Inclusion Bodies

There is abundant evidence that the small granulocorpuscles, first fully described by Miyagawa, represent the causal agent of LGI. These granules can be found lying free in human and animal exudate and tissue, and characteristically in the interior of mononuclear and histiocytic cells; they measure about 0.3μ in diameter. These bodies were found by Miyagawa in many sites, for example, human, monkey, mouse, and other animal tissues, in tissue cultures, in the chorio-allantois; the presence of the bodies was shown to parallel infectivity in filtration experiments (Miyagawa *et al.*, 1935 *a, b, c, d*, 1936 *a, b*).

Independent proof of the etiological rôle of Miyagawa's granulocorpuscles has been furnished by many workers (Coles, 1936; Satani and Sano, 1936; Tasaki, 1936 *a*; Herzberg and Kohlmuller, 1937; Hoffman, 1937; Nauck and Malamos, 1937; Malamos, 1937, 1938; Caminopetros, 1938 *a*; Cottini, 1938 *a, b*, 1939 *a, b*; Melczer, 1938; Schoen, 1938 *a*, 1939 *a, c*, 1940 *b*; Gavrilof and Fester, 1939; Melczer and Dósa, 1940; Benedek and Olkon, 1941; Levaditi, 1944 *a, b, c*; and by Coutts, see below).

The appearance of the bodies is not unlike that of *Rickettsiae*, and they have been said to develop in the intestine of lice infected with pus (D'Ignazio and Codeleoncini, 1945). There is, however, no justification for classifying Miyagawa's bodies with the *Rickettsiae* (see, e.g., Nauck, 1940).

The Gamna-Favre inclusions are probably derived from the nuclei of leukocytes ingested by macrophages (Li, 1940 *b*; see also p. 773). Favre (1940 *a, b*) has pointed out that his original preparations also contained small granules similar to the Miyagawa granulocorpuscles.

Ishimitsu (1936, 1937) described large eosinophilic inclusions in histiocytes, epithelial and glial cells of mouse brain, and in human lesions. The precise nature of these bodies is uncertain, but they resemble closely the "Russell body-like" inclusions described by Coutts, and believed by him to be viral in origin (see below).

Developmental Cycle

1. *In animals.* Findlay, Mackenzie, and MacCallum (1938 *a, b*) have postulated the existence of a definite life-cycle, analogous to that of psittacosis. Their experiments were performed on mice inoculated intracerebrally. Brains were removed and smears made at intervals from 2 hours onwards. Two main types of body were found, small and large, with the following characters:

The small forms, or elementary bodies, occur as granules intracellularly, or lying free. When inside polymorphs or mononuclears, the bodies are either diffuse, or, more usually, in small clusters. In some cases these clusters become large, and occupy a vacuole in the cytoplasm. This may rupture allowing the cluster of EB's to escape. The bodies found lying free may be diffuse or in clusters. The small forms stain bluish-gray by Castañeda's method.

The large forms are most numerous within 24 hours of inoculation, are three to four times the size of EB's, and stain reddish-purple by Castañeda. They are

arranged in a variety of ways (*a*) they may be found as compact "morula-like" ... hundreds of elementary bodies. (*b*) they may occur in groups
ion in preparations made
er inoculation, large and
lying free.
the smaller, dumb-bell
forms were seen, and also structures of intermediate size, large bodies were seen with short chains of smaller granules attached Findlay visualized the state of affairs as follows After injection the elementary bodies are too scanty to be seen for a few hours, then from the smaller forms which are injected appear large forms. These large forms now divide to form a compact mass, probably inside cells Large forms break away and penetrate fresh cells, to divide up with the production of elementary bodies Eventually only the small forms can be found, the larger "parent" bodies being no longer visible.

Somewhat similar forms have been observed by Gavrilof and Fester (1939) and Coutts (see below).

(2) *In tissue cultures* Similar developmental forms have been observed in tissue cultures (Malamos, 1938, Manabe, 1939 *a*, *b*); homogeneous inclusions in the early stages were observed to become vacuoles containing numerous EB's.

(3) *In eggs* The development cycle can be readily observed in infected yolk sacs (Rake and Jones, 1942; Shaffer *et al*, 1944, Coutts, see below) Rake and Jones found that following the disappearance of the inoculated virus bodies, new forms appeared in yolk sac cells 10–12 hours after the inoculation. These "initial bodies" divided into coccal forms and became arranged within the limiting membrane of a vesicle By 20 hours there was a further increase in size, accompanied by a considerable increase in infectivity; definite EB's were found within large green plaques, or lying free in larger masses The plaques seemed to be produced by enlargement of the larger bodies, and several might appear in one vesicle The EB's escaped to invade fresh cells 28–30 hours after inoculation

(4) *Observations of Coutts* Coutts and his collaborators have studied the morphology of LGI virus for many years, and have made numerous observations on its developmental phases in man (see above) and experimentally (see, e g, Coutts *et al*, 1939, 1942 *a*, *b*, 1943, Coutts, Lerner, and Said, 1941–2, Coutts, Luque, and Hewitt, 1940–1) For the substance of the following paragraphs, and for Figures 38 and 39, we are indebted to Dr. W. E. Coutts of Santiago who kindly sent us a personal communication (1946).

In the early stages of infection in mice inoculated intracranially with egg-cultured virus, inclusion bodies, 0 2–0 5 μ in diameter, can be observed in brain substance, lying free, or in cells. Occasionally these bodies mass together and form clusters Larger forms may appear in plaques, some of which disintegrate and

above)

Observations have also been made in yolk sacs The best results are obtained with histological material fixed in Bouin or Dubosq-Brasil and stained by Mann's method Virus bodies are difficult to find before 24 hours After this time, plaques 4–5 μ in diameter can be found lying free. Some plaques disintegrate and discharge elementary bodies to enter new cells. Occasionally larger units of 0 5–2 μ in pairs or clusters can be observed lying free.

Electron Micrographs

The EB's are similar to those of psittacosis and pneumonitis They are spherical with a dense somewhat irregular central area, and measure 438 ± 47 mμ (Kurotchkin *et al*, 1947)

Filtration

By means of filtration experiments through Gradocol membranes the : virus has been estimated to lie between 0 125 μ and 0.175 μ (Broom an 1936), and 0 1 μ and 0.14 μ (Levaditi *et al*, 1936 *a*), thus confirming observations of Miyagawa *et al.* (1935 *c*).

The virus passes through Chamberland L_2 and L_3, Berkefeld V and N, EK filters The filtrability through Chamberland and Berkefeld filters shown in 1931 independently by Levaditi *et al.* (*a, b*) and by Hellers Wassén.

OTHER PROPERTIES OF THE VIRUS

Cultivation

Tissue culture. Although Voet (1935) could not demonstrate grow other workers have obtained evidence of proliferation in media of the M Li and Rivers type (Meyer and Anders, 1932; Tamura, 1934, 1935; D'Au 1935, *Miyagawa et al, 1936 b; Gavrilof and Fester, 1939; Manabe, 1939* and Leone, 1940 *a, b*). Some of these workers have also studied the develo granulocorpuscles in slide cultures. More recently, growth has been ol embryonic tissues in serum or ultrafiltrate (Sanders, 1940, Curth, C *Sanders, 1940), and by the roller tube technique (Gey and Bang, 1939).*

Eggs. The virus can be propagated on the chorio-allantois and produc matory changes, granulocorpuscles can be found (Miyagawa *et al.*, 1935 and Malamos, 1937; Malamos, 1937; Howard and Hull, 1941, Melczer a 1941).

Although membrane suspensions contain virus, they do not make suit gens for the Frei test (Howard and Hull, 1941).

The virus grows extremely readily in the yolk sac, and produces num clusions in the entoderm, that can be readily separated and purified by sh centrifugation, the embryo is usually killed, even with inocula diluted be a preparation of purified and phenolized EB's, known as "lygranum" is e used for the Frei and complement fixation tests (Grace, Rake, and Shaf McKee, Rake, and Shaffer, 1940, Rake, McKee, and Shaffer, 1940, Shaffer, I McKee, 1940; Rake and Jones, 1942, Shaffer, Rake, and Grace, 1942, Shaf 1944)

Reaction to Physical and Chemical Agents

Cold At 4° C., material should remain active for 3 weeks, and at –1 –20° C. for over a month.

When frozen and dried *in vacuo* over sulfuric acid, infected brain i retain its activity for over 3 months (Findlay, 1933–4), although Miyaga (1935 *e*) stated that infectivity was lost after 30 to 35 days.

Heat. At temperatures from room temperature up to 30° C, the virus mains active for 24 hours, it is killed at 56° C in 10 minutes.

Glycerol. The virus only retains its activity for from 7 to 14 days (1933–4)

Storage is best carried out, therefore, by placing material in the refrig it is to be used within the next few days. To keep virus alive for several it is best to freeze and dry *in vacuo* Durieux (1945), for example, found survive for about 2 years *Infectivity is well preserved in the dry ice box.*

Chemicals The virus is destroyed by formalin (1/1,000), and attenu phenol and sodium ricinoleate (1 1,000) (D'Aunoy and von Haam, 1936 destroyed by 2 per cent urea (Nigg, 1942, Nigg, Hilleman, and Bowser *but not by bile* (Sterzi, 1939 *a*).

Radiation The virus is destroyed by the photodynamic action of methylene blue, and by ultraviolet light (D'Aunoy and von Haam, 1936 *b*)

Association with Other Infections

It has been reported (Vieuchange, 1936) that the association *in vivo* or *in vitro* of poliomyelitis and LGI viruses does not prevent the subsequent development of the typical LGI reaction in mice, nor does it allow poliomyelitis virus to become adapted to the mouse.

Rabies virus and LGI could be passed together cerebrally in mice for many passages (Levaditi, 1942 *a*) Symbiosis was also possible with *Sp duttoni* (Levaditi and Noury, 1944 *b*). Louping ill and LGI viruses could not be passed together (Levaditi, 1942 *b*) On attempting to passage Theiler's virus and LGI intracerebraly in mice, the former rapidly overgrew the latter (Levaditi and Noury, 1944 *c*) When LGI and neurotropic foot and mouth virus were passed cerebrally in mice, the former agent disappeared (Levaditi and Noury, 1943)

Localization in Tumors

When mice were injected intracerebrally with virus, and with a sarcoma subcutaneously, virus was found in considerable quantity in the tumor (Schoen, 1937 *a*, 1938 *b*). Granulocorpuscles could also be found (Schoen, 1938 *c*, 1939 *a*). Virus was also found to localize in spontaneous tumors (Schoen, 1937 *b*)

Chemotherapy

Drugs of the sulfonamide series have been shown to exert a beneficial effect on buboes in guinea-pigs (Levaditi, 1938 *a*, *b*).

More work has been done with mice, and it has been definitely shown that sulfonamides, given orally or by injection, exert a prophylactic or therapeutic effect in mice infected intracranially or nasally (Bar, 1938, Levaditi, 1938 *b*, *c*; MacCallum and Findlay, 1938, Schlossberger and Bar, 1939, Findlay, 1940 *a*, *b*, Jones, Rake, and McKee, 1941, Levaditi and Perault, 1942, Rake, Jones, and Nigg, 1942, Andrewes, King, and van den Ende, 1943, Callomon and Brown, 1943, Rodaniche, 1943, Seeler, Graessle, and Dusenbery, 1943, van den Ende and Lush, 1943, Levaditi, Mentzer, and Noury, 1944; Jones, Rake, and Stearns, 1945; Lépine and Pavilanis, 1947). Animals apparently cured usually harbor virus in the brain or lungs. The carrier rate can be reduced by a course repeated after some weeks (Jones, Rake, and Stearns, 1945). Injected mice treated with sulfonamides still acquire resistance to reinoculation of active virus (Rodaniche, 1942) Wall (1947) found good correlation between complement fixing titers and the duration of treatment; mice treated early and long developed scarcely any antibody, those given treatment late always developed antibodies Virus could always be isolated from treated mice, but less readily after a prolonged course.

In vitro, contact of sulfonamides and virus reduces virulence when subsequently tested in mice, but is not virucidal (Holder, Levine, and Bullowa, 1942).

Andrewes, King, and van den Ende (1943) tested a large number of other chemotherapeutic drugs, but found none effective

Penicillin is toxic to mice infected with LGI intracerebrally, but it exerts some protective effect (Levaditi and Vaisman, 1945, Rake and Jones, 1946).

Chemotherapeutic experiments have also been carried out in the yolk sac of the fertile egg Sodium sulfadiazine given immediately after the injection of virus delayed death of the embryo, penicillin given up to 96 hours later did the same (Meiklejohn, Wagner, and Beveridge, 1946). Hamre and Rake (1947) found that streptomycin and streptothricin had no effect *in vitro* or in the yolk sac on the virus. They confirmed the activity of penicillin, but found that it decreased as the drug was used in increasing purity.

Relationship to Other Viruses

The interrelationship of the LGI–psittacosis–pneumonitis group is discussed in Ch. LXVII.

The virus of Durand's disease is unrelated to LGI virus (Findlay, 1942).

IMMUNITY REACTIONS

Active Immunity

Animals become resistant, even to intracerebral injection, on recovery from infection. According to Schoen (1939 *b*) no histological changes develop after the challenge dose.

In man, it seems to be doubtful whether a complete cure of LGI often results, for the Frei and CF tests frequently remain positive. This is most readily explained by the continued presence of the virus, if not in an active condition then latently. Virus was isolated from a lymph node 4 months after a full course of sulfadiazine (Heyman, Wall, and Beeson, 1947). However, in certain cases the tests do become negative, it seems reasonable to conclude that primary and secondary cases may become free of infection, although this is unlikely to occur with the later manifestations. Brandt (1941) suggests that a considerable percentage of cases heals spontaneously, especially if buboes develop.

Frei's Test

Antigens.

Human material. In the original Frei technique (1925) the antigen is prepared by diluting pus from a known case of LGI with 5 times its volume of normal saline The material is heated for 2 hours at 60° C. and on the following day for another hour As a control, heated saline is used In the test, 0 1 c.c is inoculated in the forearm It is convenient to dry pus *in vacuo* from the frozen state, and reconstitute as required (Grace, 1934). Filtrates of pus prove inactive (Paulson, 1936).

Antigen can be prepared from the feces of cases of colitis due to LGI (Paulson, 1937, 1938, 1939, Paulson and Kravetz, 1938).

CSF has been used as a source of antigen (Chevallier and Bernard, 1932, Midana and Vercellino, 1934, Koschucharoff, 1938) Ottolina (1941, 1943) has recorded the occurrence of vesicle formation when CSF is used as antigen

Reiss (1934, 1935) postulated the presence of an antigen in the serum of early cases, and claimed that such serum could be used as Frei antigen, mixed with the usual bubo pus antigen, an enhanced lesion resulted Le Gac (1936) obtained similar results, but Haynes (1935) and Howard and Strauss (1936) could not confirm these observations

Animal tissues Infected animal tissues have been recommended, and are of some value Unfortunately there is a definite tendency for nonspecific reactions to occur with the control Also, injection of animal tissue may render the patient sensitive to a further test with the same material (Jansen, 1938)

Monkey brain has been used (von Haam and Lichtenstein, 1935). Durieux (1945) recommends the use of brain desiccated *in vacuo* in individual ampules

Mouse brain has been widely employed as antigen It can be desiccated *in vacuo*, and made up into antigen as required, with saline (Grace, 1934). Mouse brain tends to produce nonspecific reactions in normal people, and chiefly for this reason has been found unsatisfactory by certain workers (e g, Strauss and Howard, 1936, Binkley and Love, 1938) Others, however, have found it satisfactory, if a potent antigen giving a papule measuring 7–10 mm is used (D'Aunoy and von Haam, 1936 *a*, Grace and Suskind, 1936 *a*, *b*, von Haam and Hartwell, 1937 *b*, Reider and Cañizares, 1938, Grace, 1939, Costello and Cohen, 1941)

Rabbit lung antigen was recommended by Caminopetros and Photakis (1935), but not by von Haam and Hartwell (1937 *a*) Guinea-pig gland was used by Grace and Suskind (1940).

Cultured virus The culture fluid in Maitland's medium has been used as antigen (Tamura, 1934), also the fluid from roller tube cultures (Gey and Bang, 1939).

Egg virus. Lygranum antigen was first introduced by a group of American workers (Grace, Rake, and Shaffer, 1940, Shaffer, Rake, and Grace, 1942, and see above) It is
the EB's by centrifugation, and
l eggs is used as control This
nd its value has been confirmed
ulkin *et al*, 1941, Axelrod, 1942,

1943; Smadel,

han to mouse
occur, due to
ygranum is as
vided a papule
measuring 7 mm. is regarded as the minimal size of a positive reaction

A saline suspension prepared from yolk sacs heavily infected and inactivated with 2 per cent. urea or 0 5 per cent. phenol has been found satisfactory (Nigg, Grace, and Hilleman, 1947).

Reaction to Frei's Test

In cases of LGI, following the inoculation of antigen, an area of erythema results with central papulation The test should be read after 48 hours It is generally believed that in true positive reactions the papule measures 7 mm or more. Unfortunately, doubtful reactions up to 4–5 mm in diameter may occur in uninfected persons, or may be given by the control material as well.

The reaction becomes positive 2–6 weeks after onset in a very high percentage of cases, false positives, if a sizeable papule is produced, are rare (Frei, 1932 *a*, *b*, 1933, de Wolf and van Cleve, 1932, Jersild, 1933, Bacon, 1935, Lebeuf, 1939). Negative results in definite cases are unusual, and are usually due to factors tending to reduce dermal sensitivity

The intradermal Frei test may cause an exacerbation of the disease, but serious reactions are very rare A most unusual case was reported by Keim and Wakefield (1939), where flaccid paralysis developed 11 days after the use of a mouse brain antigen injected intradermally.

It is probable that despite apparent cure, even with sulfonamides, the Frei test remains permanently positive (David and Loring, 1936, Grace, 1941 *a*, Heyman,

and Monetta, 1938, Michelson *et al*, 1938, Monetta and Coutts, 1941, Axelrod, 1942).

Histological appearance.

The papule in a positive case shows cellular infiltration and necrosis (Kornblith, 1936) Smith (1940) has reported that after 24 hours the epidermis shows marked edema, spongiosis, and almost vesiculation, the cutis shows edema, and there is an accumulation of lymphocytes and a few polymorphs in the perivascular spaces After 72 hours, there is slight hyperkeratosis and some epidermal edema. In the cutis, there is a noticeable increase in connective tissue cells, the perivascular spaces show a definite infiltration with lymphocytes The appearances after 5 days are similar, with less epidermal edema and spongiosis

The nature of the intradermal Frei test.

It is presumed that the Frei test is a sensitivity phenomenon dependent on the presence of a focus of infection with the virus of LGI Frei antigen does not contain living virus. Seitz filtrates of EB suspensions elicit the reaction, perhaps due

Relationship to Other Viruses

The interrelationship of the LGI–psittacosis–pneumonitis group is disc in Ch. LXVII.

The virus of Durand's disease is unrelated to LGI virus (Findlay, 1942).

IMMUNITY REACTIONS

Active Immunity

Animals become resistant, even to intracerebral injection, on recovery fron fection According to Schoen (1939 *b*) no histological changes develop after challenge dose.

In man, it seems to be doubtful whether a complete cure of LGI often res for the Frei and CF tests frequently remain positive. This is most readily expla by the continued presence of the virus, if not in an active condition then later Virus was isolated from a lymph node 4 months after a full course of sulfadia (Heyman, Wall, and Beeson, 1947). However, in certain cases the tests do bec negative, it seems reasonable to conclude that primary and secondary cases become free of infection, although this is unlikely to occur with the later mani tations Brandt (1941) suggests that a considerable percentage of cases heals sp taneously, especially if buboes develop.

Frei's Test

Antigens.

Human material In the original Frei technique (1925) the antigen is prepared diluting pus from a known case of LGI with 5 times its volume of normal saline material is heated for 2 hours at 60° C and on the following day for another h As a control, heated saline is used In the test, 0 1 c c is inoculated in the forearm I convenient to dry pus *in vacuo* from the frozen state, and reconstitute as required (Gr 1934). Filtrates of pus prove inactive (Paulson, 1936)

Antigen can be prepared from the feces of cases of colitis due to LGI (Paulson, 1 1938, 1939, Paulson and Kravetz, 1938)

CSF has been used as a source of antigen (Chevallier and Bernard, 1932, Midana Vercellino, 1934, Koschucharoff, 1938) Ottolina (1941, 1943) has recorded the occurre of vesicle formation when CSF is used as antigen

Reiss (1934, 1935) postulated the presence of an antigen in the serum of early ca and claimed that such serum could be used as Frei antigen, mixed with the usual bu pus antigen, an enhanced lesion resulted Le Gac (1936) obtained similar results, I Haynes (1935) and Howard and Strauss (1936) could not confirm these observatio

Animal tissues Infected animal tissues have been recommended, and are of some val Unfortunately there is a definite tendency for nonspecific reactions to occur with t control Also, injection of animal tissue may render the patient sensitive to a furth test with the same material (Jansen, 1938)

Monkey brain has been used (von Haam and Lichtenstein, 1935) Durieux (194 recommends the use of brain desiccated *in vacuo* in individual ampules

Mouse brain has been widely employed as antigen It can be desiccated *in vacu* and made up into antigen as required, with saline (Grace, 1934) Mouse brain tends produce nonspecific reactions in normal people, and chiefly for this reason has be found unsatisfactory by certain workers (e g, Strauss and Howard, 1936, Binkley ar Love, 1938) Others, however, have found it satisfactory, if a potent antigen giving papule measuring 7–10 mm is used (D'Aunoy and von Haam, 1936 *a*, Grace and Su kind, 1936 *a*, *b*, von Haam and Hartwell, 1937 *b*, Reider and Cañizares, 1938, Grace, 193 Costello and Cohen, 1941)

Rabbit lung antigen was recommended by Caminopetros and Photakis (1935), but n by von Haam and Hartwell (1937 *a*) Guinea-pig gland was used by Grace and Suskin (1940)

Cultured virus The culture fluid in Maitland's medium has been used as antige (Tamura, 1934), also the fluid from roller tube cultures (Gey and Bang, 1939).

Nigg, Hilleman, and Bowser (1946) found that antigenicity was enhanced by phenolizing yolk sac suspensions at once and incubating at 37° C for 22–60 days. Boiling induced the same degree of enhancement. Autoclaving phenolized suspensions also induced enhancement. They concluded that the mechanism of enhancement by heat or phenol was the same. Perhaps these agents dissociate a protein-polysaccharide-lipoid complex responsible for CF, and the greater dispersion of the antigen accounts for the enhancement. Alternatively an inhibiting factor may be inactivated.

Experimental.

Complement fixing antibodies develop in the sera of rabbits, mice, hamsters, and other rodents immunized with inactivated or active virus (Hildebrand, 1936; Eaton, Martin, and Beck, 1942) In mice that recover, antibodies can be found two weeks after inoculation (Wall, 1947).

In man.

A number of workers has detected complement fixing antibodies in convalescent serum using Frei antigen, or gland antigen (Hecht, 1935, Coutts and Ponce,

man and Webb, 1946, Shaffer and Rake, 1947).

Bowser and Nigg (1946) found that the majority of sera from cases of primary and secondary syphilis reacted in CF tests with specific and control boiled phenolized yolk sac antigens, nonspecific reactions appeared to be eliminated by using the supernatant of boiled phenolized antigen.

In CF tests with lygranum, serum is often used diluted ⅕ only. Dulaney and Packer (1947) found that in this dilution nonspecific reactions tended to occur in healthy persons, in persons suffering from upper respiratory infections, and in the presence of other venereal infections They concluded that fixation with a serum

certain cases of syphilis Where there is a double infection, such absorption leaves the reaction with lygranum unaffected.

Grace, Shaffer, and Rake (1943) concluded that the explanation of the majority of unsuspected positive reactions was the existence of latent LGI This is confirmed by the fact the sera of cases of congenital syphilis rarely fix complement with lygranum (Shaffer and Rake, 1947). Prolonged sulfonamide therapy may not remove CF antibodies, suggesting the continuance of infection (Grace and Rake, 1943)

The children of Frei-positive mothers show complement fixing antibodies in the first 2–3 months of life, but these disappear thereafter (Levine, Bullowa, and Scheinblum, 1943, Beeson and Miller, 1944 *b*).

to the presence of a soluble antigen (Rake *et al.*, 1941 *b*). The pus in the center of a Frei reaction still contains antigen in an active form (Strauss and Howard, 1934). Injection of serum of Frei-positive cases into healthy persons causes them to react positively, the Prausnitz-Kustner technique can be used to demonstrate transmission of sensitivity (Melczer and Sipos, 1938 *a*, Marks, 1942). It has been stated that convalescent serum neutralizes the activity of the Frei antigen (Gottlieb, 1932 *a*, Tasaki, 1937 *a*); but others have failed to confirm this observation (Calatayud, 1933, Haynes, 1935).

The reverse Frei test.

Antigen can be prepared from the suspected case and injected into a known case (Wiedmann, 1935).

The intravenous Frei test.

Following intravenous injection of Frei's antigen, pyrexia develops in a few hours, and this may be of diagnostic significance (Tasaki, 1937 *b*). Mouse brain antigen can be used (Decker, Cañizares, and Reider, 1939, Costello and Cohen, 1941; Morris and Cañizares, 1942).

Virus Neutralizing Antibodies

Experimental.

Virus neutralizing antibodies can be produced in rabbits inoculated with living or formolized virus, but only with difficulty (Okanishi, 1937, van den Ende and Lush, 1943). Mice convalescent from infection develop neutralizing antibodies (van den Ende and Lush) These workers titrated antibody by inoculating mixtures of a pneumotropic strain and serum nasally in mice, the number of foci of consolidation being counted

Convalescent serum was found not to protect against experimental infection in guinea-pigs (Caminopetros, 1939).

In man.

Although Hildebrand (1936) could not demonstrate neutralizing properties in human convalescent serum, other workers have detected these antibodies (Levaditi *et al*, 1932 *a*, *c*, *e*, Miyagawa *et al*, 1935 *e*, Wassén, 1935, Tasaki, 1937 *a*, Caminopetros, 1938 *b*, Gey and Bang, 1939, Rodaniche, 1940, Menk and Mohr, 1941, Frei, 1943; Grace, Shaffer, and Rake, 1943)

Rodaniche used a mouse brain virus, and injected mixtures intracerebrally

Complement Fixation

Nature of the reaction.

Complement fixation can be demonstrated between convalescent or hyperimmune sera and various types of LGI antigen Thus infected lung or gland tissue has been used (see below). Fixation can also be demonstrated between sera and the Frei reagent prepared from pus Infected yolk sac material (lygranum) in the form of an untreated suspension, will fix complement, purified EB's also fix complement. Further, there is a soluble complement fixing antigen in yolk sac suspension (which also elicits the Frei reaction), for filtrates or supernates are active (Rake *et al*, 1941 *b*, Nigg and Bowser, 1943) Part of the complement fixing antigenic material is resistant to boiling (Nigg and Bowser, 1943)

The CF properties of infected yolk sac material can be enhanced in various ways. Thus, treatment of a crude suspension with phenol, urea, or ether yields a better antigen than is afforded by EB's (Nigg, 1942, Nigg and Bowser, 1943, Hilleman and Nigg, 1946)

BIOLOGICAL PRODUCTS IN THE TREATMENT OF LGI

E

rout

and

blith, 1939). Caminopetros (1939) recommended the injection of antigen into the bubo and rectal tissue and claimed more rapid healing Tamura (1935) suggested the use of heated culture virus. Jonesco-Mihaiesti *et al.* (1934) recommended a heated vaccine prepared from the organs of a monkey injected intraperitoneally. Filtrates of ground infected glands have been used by Zahawi and Akrawi (1940).

Pyrexia produced by TAB or Dmelcos vaccines is said to be beneficial (Batchelor, 1937).

Numerous workers have found the sulfonamide drugs to be effective, apparently even in the later stages. As the Frei test may remain positive after treatment, it is doubtful whether the infection is entirely eliminated (Earle, 1939, Hebb, Sullivan, and Felton, 1939, Midana, 1940; Brandt and Greenblatt, 1941, Schamberg, 1941, Stammers and Law, 1942, Pico Estrada, Lima, and Calcagho, 1945, Wall, 1946).

Normally sulfonamide destroys the infectivity of virus in buboes in 2–3 weeks, in one case, however, virus was isolated 4 months after a full course (Heyman, Wall and Beeson, 1947).

Penicillin has been reported on favorably, used locally or by injection (Willcox, 1946, Mayne and Bain, 1947).

Antimony appears also to be useful.

Human convalescent serum was found effective by Videla and Capulo (1939), but animal serum proved too toxic (Sagher, 1944). Caminopetros (1939) did not find human serum to be of value.

LABORATORY DIAGNOSIS

(*a*) *Routine bacteriological examination* Films of pus should be thoroughly examined for organisms, including Ducrey's and tubercle bacilli. Cultures should be prepared aerobically and anaerobically, not omitting the special rabbit blood technique for Ducrey's bacillus as used by Nicolle (1923). Supposing no organisms are found by this examination, one is fully justified in proceeding to special diagnostic measures.

(*b*) *Frei's test should be carried out with lygranum or other antigen, and suitable control material.* If desired, antigen can be prepared from mouse brain infected with the patient's material and used in known cases of LGI (Frei, 1943). It may be necessary to carry out the reverse Frei test, i e., preparing antigen from the pus of the suspected case, and injecting it intradermally in a known case.

(*c*) *Animal experiments* Monkeys and mice are injected intracerebrally, and guinea-pigs in the groin with pus, at least 4 guinea-pigs and 6 mice being injected. *It should be remembered that the rhesus monkey is not nearly so susceptible as the* green or callithrix monkey. Pus for inoculation should be diluted 1/10–1/20 in saline, and shaken mechanically with glass beads, lymph nodes should be ground and lightly centrifuged (Wall, 1946) Saline can be inoculated into buboes or lymph nodes, and aspirated (Heyman, Wall, and Beeson, 1947).

Coutts (1946) recommends the inoculation of pus, or the implantation of tissue in the anterior chamber of the rabbit's eye. After 3–5 days the contents are inoculated in the yolk sac.

(*d*) *Inoculation of eggs and tissue cultures* Virus can be isolated by direct inoculation of bubo material in the yolk sac (Shaffer, Rake, and McKee, 1940, Shaffer *et al.*, 1944) If no EB's are seen at the primary inoculation, 4–5 "blind" passages should be carried out (Wall, 1946) Virus may also be isolated by direct inoculation in tissue cultures (Sanders, 1940)

(*e*) *Serological tests* A complement fixation test should be carried out with lygranum antigen Wassén (1935) and Frei (1943) have used virus neutralization tests Antigen from the patient can be tested with animal antiserum to see if complement is fixed (Frei, 1943).

(*f*) *Histological examination* Coutts (1946) recommends that smears, e g, of *bubo pus, are fixed in Bouin or Dubosq-Brasil, and stained with 3 per cent.* magenta or 2 per cent mercurochrome with nigrosin background, or by Mann's stain. For sections, the same fixatives should be used Mann's or Machiavello's stains give the best results, stained by Mann's method, inclusions stain indigo or purplish-blue.

(*g*) *Other tests* The blood should be examined by count and biochemically.

(*h*) To exclude syphilis, the Wassermann and flocculation tests should be performed, and to exclude ulcus molle (soft sore, chancroid) 0 2 c c. of Ducrey's bacillus vaccine should be injected intradermally A positive reaction to this Reenstierna's test is indicated by the formation of a wheal and erythematous halo in 24 to 48 hours, perhaps with a rise of temperature up to 102° F This reaction denotes the existence, past or present, of a Ducrey infection (see, e.g, Lees, 1937) It is not *at all easy, however, to separate LGI and Ducrey's infection* There is no doubt that a considerable number of colored persons are infected at the same time with these diseases, and probably with syphilis also (Brandt and Torpin, 1940, Robinson, 1940, Young, 1944)

the coexistence *of positive skin* tests t co-reactions can occur in the acute ur in soft sore, positive CF tests for LGI may also occur (Brandt and Torpin, 1940, Heyman, 1946).

head, 30 days, upper extremity, 50 days, and leg, 44 days (see also Dodero, 1937 *b*, Jordan, 1939, Boecker, 1940).

Livon and Placidi (1929) reported a case developing 13 days after a face bite (see also Wright and Gosden, 1946). Proca and Bobes (1940) found that short incubation periods were more frequent in Bucharest than elsewhere, and that short incubations were more frequent in children under 15 years than in older persons.

Various cases developing after a prolonged incubation period have been reported: e g, after 9 months (Jagot, 1886), after 1 year, although antirabies treatment was administered following the bite (Rochaix, 1924, Stuart and Krikorian, 1932 *b*), after 14 months (Hajare, 1933), after over 3 years and 2 months, although antirabies treatment was administered (Iyengar, 1935).

Certain street viruses have properties very similar to those of *virus fixe*, including a short incubation period in animals It was suggested by observers in Tonkin that the reason why the local incubation period was short (under 4 weeks), and antirabies treatment often failed, was because of the prevalence of these virulent *renforcé* strains (Bablet and Joyeux, 1930, Genevray and Dodero, 1934; see also Dodero, 1938 *b*) However, this concept does not seem to be generally accepted.

Manifestations of Human Rabies

Although furious rabies is the commonest manifestation, other types may occur. It is not proposed to give the clinical features of classical rabies in great detail, as these are well known. Attention will be concentrated on certain aspects of the disease less well recognized

1. Furious rabies.

Prodromal symptoms The patient frequently feels pain at the site of the wound, is restless, suffers from headache and complains of aching in the back and limbs

Course of the disease. The characteristic symptoms of hydrophobia soon develop At first, the hydrophobic attacks occur only on attempts being made to drink, when the head is thrown back, the eyes are fixed, and the hands may go into spasm. The patient has a dread of water and shudders at the very sound of the word Later, the spasms are more readily provoked by drafts or loud sounds, and swallowing becomes almost impossible The patient is very dyspneic, especially on inspiration, and the respiration rate is rapid, while Cheyne-Stokes rhythm may occur The patient usually expectorates freely and saliva is ejaculated in all directions, sneezing may be a prominent feature With the progress of the infection the patient becomes noisy, restless, and often actively "furious," breaking articles of furniture and even attacking bystanders. Attempts may be made to bite. The mind is lucid between the attacks, but as these become more frequent the mental derangement increases and hallucinations and delusions may be experienced (Figs 40A and B). Aerophobia can be demonstrated by waving a fan before the face.

After a leg bite the first symptoms may be referable to the lumbar cord, such as dysuria and disorders of defecation After an ear bite cerebellar symptoms have been recorded. The temperature is usually raised, especially before death, and may continue to rise thereafter (see, e g, Gamaleia, 1887 *a*, Schaffer, 1890). The pulse is usually increased in rate The pupils are usually dilated but may contract and dilate alternately. The reflexes are increased at first, but later become absent. If the patient lives long enough, paralysis of the limbs usually occurs as a terminal event. Newborn children of rabid mothers seldom, if ever, contract the infection (see, e g, Genevray and Dodero, 1935) Blatt *et al* (1938) have published some informative pictures of rabies cases

2. Spinal manifestations.

(*a*) *The landriform type* This type of rapidly ascending and usually fatal paralysis has been recorded from time to time in cases of untreated rabies (e g,

CHAPTER LXXIII

RABIES (HYDROPHOBIA) IN MAN

Rabies is a disease of great antiquity; it was known in the time of Aristotle, Pliny, and Celsus, and has remained endemic in various parts of the world to this day. The disease is primarily one of animals—mainly dogs, cats, herbivora, and certain carnivora; man is usually infected by a bite of a rabid animal Great interest has been taken in a form of rabies in Trinidad, the transmitting agent being a bat.

Little progress was made in the isolation of the etiological agent of rabies until, towards the end of last century, it was found that animals, especially dogs and rabbits, could be infected with human nervous tissue. The next step was Pasteur's claim that dogs could be actively immunized with cords of attenuated virulence. Later, he applied this discovery to the treatment of bitten persons. The etiological agent of rabies is now well recognized to be a filtrable virus. Despite over 40 years' research, however, the precise significance of the characteristic inclusion body—the Negri body—is still uncertain.

With regard to the literature, this has reached vast proportions, and particular mention should be made of the excellent reviews published twice yearly from 1924–43 by A. G. McKendrick, and since then by I A. Galloway in the *Tropical Diseases Bulletin*. Schweinburg (1937)[1] has published a very lengthly review of modern work. A prominent part in experimental study has been played by MM. Remlinger and Bailly of Tangier, and many of their researches have been collected together (1938 *a*).

CLINICAL FEATURES

Factors Predisposing to Rabies

There has been some discussion as to whether certain factors may predispose to rabies, or modify the resultant type of the disease Thus, in the days of Gamaleia (1887 *c*) alcohol was definitely blamed as a predisposing cause of rabies, but experimental work (see p. 847) has shown that this is unlikely. The nervous constitution of the bitten person plays a part in determining the type of rabic syndrome —furious or paralytic—which develops Persons infected with virus and given anti-rabies treatment may develop rabies a considerable time later if subjected to an emotional shock (Remlinger, 1946 *b*) On the whole, however, there are no predisposing factors of any great importance

Incubation Period

It has been held that the nearer the bite is to the central nervous system, the shorter is the incubation For example, Webster (1944) gives the following figures for the average incubation periods face, 30 days, arm, 40 days; leg, 60 days Johnson (1943), however, disputes this, and suggests that the amount of virus introduced and the type of tissue involved are the chief determining factors, the incubation period after head and face wounds is usually short because of severe laceration and exposure of sensory nerves. Johnson gives the following average incubation periods

[1] References are appended at the conclusion of Ch LXXIX, p. 887 et seq

(*b*) *Transverse myelitis* Roy (1936) described a case, at first thought to be idiopathic transverse myelitis, which developed definite hydrophobic symptoms shortly afterwards.

3. Paralytic rabies.

The first description of paralytic rabies in man is said to have been that of van Swieten (see Brouardel, 1897) However, until the description of Gamaleia (1887 *a*, *c*, *e*) no form of human rabies other than the hydrophobic type was generally recognized Since that date other similar cases have been recorded (see e g, Van Gehuchten, 1907, Koch, 1912, Babès, 1912 *a*, Marie and Chatelin, 1919, van Wulffren Palthe, 1930, Love, 1944). The usual symptoms presented by such cases are pyrexial disturbance, paralysis of the limbs, paraplegia, paralysis of the face and eye muscles resulting in ptosis and strabismus, fibrillary tremors, irregular respirations with respiratory spasms, and dyspnea, priapism and ejaculations, sensation is usually preserved, but some cases are anesthetic, pains may occur in the limbs later to be paralyzed. Hydrophobic symptoms may be absent in such cases The histological features of paralytic and furious rabies would appear to be similar and are described on p 797 (see Van Gehuchten, 1907, Higier, 1912, Federoff, 1925–6, Marie and Chatelin, 1919)

The above description applies to paralytic rabies contracted from rabid dogs and other animals, and should not be confused with paralytic rabies occurring in Trinidad, spread by bats.

CLINICAL PATHOLOGY

The blood A number of workers has reported the hematological findings in untreated cases of rabies (e g, Courmont and Lesieur, 1901, Leger, 1923, Jonnesco, Valter, and Teodisiu, 1927, Massias, 1928). Differential counts usually show a relative, and sometimes an absolute, increase in polynuclears Monocytes and eosinophils are usually diminished, and this change appears some 2 days before the onset of symptoms The BSR is said to be increased (Stanesco and Enachesco, 1939)

The cerebrospinal fluid is usually normal, although an increase of leukocytes up to 100 per c mm has been reported (see e g, Lesieur, 1904, Marie and Chatelin, 1919, Wright and Gosden, 1946)

The urine is usually loaded with albumin, and may contain sugar (see, e g, Southam, 1879)

DISTRIBUTION OF STREET VIRUS IN THE BODY

Site of bite The virus has been found in the scar (Pace, 1903), but may not be present in all cases (Sabin and Ruchman, 1940)

Central nervous system In the past it has been stated that virus is found most constantly in the medulla (Gamaleia, 1887 *c*, Pace, 1903), but it is doubtful if this is correct Employing the sensitive mouse inoculation method, Leach and Johnson (1940 *a*) found virus in the anterior central gyrus, thalamus, pons, medulla, and spinal cord of 3 cases, the thalamus titered 10^{-4} in all cases Virus may also be found in Ammon's horn and the olfactory bulbs (Sabin and Ruchman, 1940)

Paltauf (1909) claimed to have found street virus in the brain of persons who died from intercurrent diseases early in antirabies treatment

Virus does not occur in the cerebrospinal fluid

Nerves Pasteur, Chamberland, and Roux (1884) reported that virus could be obtained from the vagus and sciatic nerves of human cases of rabies After a bite on one leg, virus has been found in the corresponding sciatic nerve and frequently in the contralateral nerve as well (Pace, 1903)

Roux (1888 *a*, 1889) reported that he had found virus in the axillary nerves

Remlinger, 1906 *c*; Lemke, 1934; Fife, 1945). It should not be confused with the ascending paralysis which may complicate antirabies treatment as a neuroparalytic accident (see Ch. LXXIX).

Knutti's (1929) case illustrates the symptomatology of acute ascending paralysis. The case was remarkable in that although the virus of rabies was isolated there was

Fig 40 Case of rabies in an Egyptian woman, exhibiting symptoms of hydrophobia. In A, the patient is shown refusing to drink water In B, she has taken a sip of water, and the photograph taken immediately afterward illustrates the facial appearances during a hydrophobic spasm

(Photograph by the authors, reproduced by courtesy of Dr Ibrahim Shahin, Director, Antirabies Institute, Cairo.)

no history of a bite from a rabid dog Apparently, however, the patient had been bitten by a squirrel (Love, 1944) The illness started with some pain in the left leg and lower abdomen The leg soon became numb and spastic, and the patient felt depressed mentally, next, the leg became partly anesthetic and showed a flaccid paralysis The paralysis then spread to the other leg Just before death the hands had become numb also The ganglion cells of the cord, especially in the anterior horn, showed all degrees of degeneration, most of the motor cells having been completely destroyed The nerves arising dorsally showed areas of degeneration with loss of myelin, sometimes this loss was almost complete, only a shell of tissue remaining around an infiltration of mononuclears and phagocytes

The rabic nature of this most interesting case was established by finding Negri bodies in certain anterior horn cells, and by transmitting the infection to rabbits by scarifying the skin with a cord suspension

mal, there the virus presumably invades the terminal nerve filaments Some local pullulation may take place, as virus has been isolated from the bite wound even when scarred (Pace, 1903). The infecting animal does not necessarily need to bite, as cases of rabies developing after clawing and scratching only have been recorded (e g., by Remlinger, 1906 *b*, Kocevaloff, 1923) In other cases it appears that rabies may be contracted by the virus passing through the unbroken skin, although such an occurrence must be regarded as a rarity. Thus, Stuart and Kirkorian (1932 *b*) reported a case following on soiling of the apparently unbroken skin of the hands with the saliva of a rabid calf. Greval (1936) recorded cases following on the licks of rabid dogs (see also Shields, 1939). Glusmann (1928) reported a case of rabies with no history of contact with a rabid animal. We ourselves observed a fatal case in a veterinary surgeon returned from East Africa, who as far as he was aware had not been exposed to infection from a mad dog.

Spread of the virus in the body. Having gained entrance through a wound made by a bite, scratch and claw, or, rarely, through the unbroken skin, it is believed that the virus ascends in the nerve trunks This theory is based on various facts. Thus, Pasteur, Chamberland, and Roux (1884) reported that virus had been isolated from human vagus and sciatic nerves. Roux (1888 *a*, 1889) was able to isolate virus from the axillary nerves, following an arm bite, the virus was absent from the radial nerves, suggesting that it had passed centrally Roux also noted that virus might be found in the nerves of the healthy side, clearly suggesting a general dissemination throughout the peripheral nervous system. Virus was isolated from both sciatic nerves after a bite on one leg only (Pace, 1903)

Additional evidence that spread occurs along nerves is afforded by the fact that, following leg bites, the first part of the central nervous system to be involved is often the lumbar cord, producing symptoms of dysuria and disorders of defecation. Correspondingly, following ear bites, the cerebellum may be the first part of the central nervous system to be affected Further, in cases that have died early, it has sometimes been possible to observe that the main pathological changes in the central nervous system occur in the cord corresponding to the bitten limb Histological changes have been observed in the nerves and spinal ganglia corresponding to the bitten limb (see e g, Marinesco and Draganesco, 1932)

Manouélian (1936 *b*, *d*) has found Negri bodies in the endoneurocytes of the sensory and sympathetic fibers of the face, and in the sympathetic ganglia in cases of rabies This certainly suggests that virus diffuses through the peripheral nervous system (*septinévrite*) in man, as in animals

Despite the above observations, the question is in need of review, using more sensitive methods In particular, the rôle of blood and lymph requires investigation There are evident similarities to the much debated question of the spread of tetanus toxin

PATHOLOGY

1. Central Nervous System

The general neuropathological features of rabies have been described by numerous authors (e g, Benedikt, 1874, Schaffer, 1889, 1890, Fañanás, 1918, 1922, Marie and Chatelin, 1919, Krinitzky, 1926, Lowenberg, 1928, Bassoe and Grinker, 1930, Rojas, 1932, Riesman *et al*, 1933, Verhaart, 1934, Schukru-Aksel, 1934, 1935–6, 1937–8, Tinel, 1938, Rodriguez, 1943, Costa and Netto, 1944) Certain authors give references to earlier workers (see Van Gehuchten and Nelis, 1900 *a*, Federoff, 1925–6)

Nerve cell lesions A number of authors has described changes in the nerve cells of a varied nature (see e g, Bosc, 1903 *a*, Marinesco, 1909, 1910, Marie and Chatelin, 1919, Marinesco and Draganesco, 1932, Riesman *et al*, 1933). Thus the Nissl bodies are often lost, the cells vacuolated, and the nuclei degenerated Cajal's

following an arm bite He also mentioned that the virus might be found in the nerves of the unbitten side Bardach (1888) also isolated virus from a nerve, central to the site of a bite.

Saliva. Suitable inoculation tests have demonstrated the infectivity of the human saliva [illegible] 1881 *a*, Raynaud and Lannelongue, 1881; [illegible] 1931 *a*, 1933, Sulkin and Harford, 1943; [illegible]

Sec[illegible]s, been isolated from the lacrymal, *parotid, sublingual, and submaxillary glands* (Pasteur, Chamberland, and Roux, 1884; Bardach, 1888, Pace, 1903, Tscheschkow, 1931; Leach and Johnson, 1940 *a*).

Urine. Virus has been found in the urine (Jonnesco, 1927 *b*).

Milk. The milk of a lactating woman was found to contain the virus (Bardach, 1887 *b*).

MORTALITY

Once rabic symptoms develop the disease is uniformly fatal. Although death does not usually occur until the disease has lasted for some few days, sudden death *may occur in the early stages, and Bobes (1928) has suggested that this is due to an* affection of the cardiac nerves.

Owing to the large number of variable factors, it is extremely difficult to assess the chances of a completely untreated person dying of rabies from the bite of an infected animal Cornwall (1923) suggested that strains of virus vary in infectivity, and quoted a series of 423 untreated persons bitten by rabid dogs, with 35 per cent. mortality. On the other hand it is known that many persons bitten by rabid dogs and untreated escape infection (see e.g., Breault, 1945), and Cornwall's figure is probably well above the average. It would seem reasonable to suggest that no more than 5–15 per cent. of persons bitten by rabid dogs, and untreated, actually develop rabies, this figure being influenced by various factors

With regard to the severity of the bite, reporting Kasauli deaths, Harvey and McKendrick (1923) found a deep bite to be 4 8 times as serious as a superficial one. They also noted that efficient and timely cauterization lowered the deaths in the proportion of 4 3 and interposition of clothing by 6 6 1, the site of the bite is also of importance, the proportional mortalities according to the site being face 7.7, arm 1.15, and leg 0 7.

Wolf bites are more serious than dog bites, and the mortality in untreated cases is at least 60 per cent.

Further information on mortality will be found in the section on antirabies treatment (see p. 868)

PATHOGENESIS

Experimental It is generally conceded that rabies virus spreads from the portal of entry to the central nervous system by the nerve fibers This view *is largely* based on experimental work (see p 828)

It has been found that experimental animals can be very readily infected by intraneural injection After such inoculation, as after intracranial injection, virus spreads throughout the whole nervous system and can be isolated from the brain, sciatic, median, and other nerves This spread is termed *septinévrite*, and takes a few days. Thus, after intraneural injection virus cannot be demonstrated in the brain or other nerves for 5 to 6 days After intracranial injection virus cannot be found in the peripheral nerves for a similar number of days Experiments undertaken in animals with divided nerve tracts have shown that this operation effectively prevents virus reaching the portion distal to the site of inoculation.

Portal of entry of the virus Virus usually enters the body through the skin, being deposited in the depths of a wound by the infected saliva of the biting ani-

by leukocytes, especially in the anterior horn, perivascular cuffing, general congestion, and hemorrhages are also found, these hemorrhages are said to be most marked *posteriorly*. *The anterior horn cells are usually degenerate, and this process frequently* affects the white fibers also Generally speaking, the inflammatory changes are most marked in the gray matter. The portion of the cord most involved, both naked-eye and microscopically, is often that corresponding to the bitten limb, i e., the lumbar cord in leg bites and the cervical cord in arm bites *(see, e g, Schaffer,* 1889)

Midbrain Cellular infiltration and hemorrhage usually occur in the pons and *basal nuclei In certain cases the substantia nigra and neighboring nuclei may be* markedly involved in the inflammatory reaction. Thus, Slotwer (1926) gives the following sites where cellular changes may be marked substantia nigra, "supraoptic" nucleus, paraventricular nucleus, grisea centralis, and corpus luysi (see also Lowenberg, 1928) In the substantia nigra there is often marked neuronophagia of the pigmented cells

Cerebellum Changes in the cerebellum may occur, especially after bites on the *ear (see Gamaleia, 1887 a, Marie and Chatelin, 1919). The Purkinje cells may* be destroyed, and undergo neuronophagia.

Cerebrum Beyond some congestion, and the occasional presence of Negri bodies or degenerate neurons, there is little to be seen

Differential diagnosis Various authors have likened the lesions of rabies to those of epidemic encephalitis (see, e g, Klarfeld, 1922, Schukru-Aksel and Spatz, 1925, Lowenberg, 1928, Bassoe and Grinker, 1930, Rojas, 1932). This likeness is most evident when the lesions are prominent in the substantia nigra and neighboring areas. The presence of Negri bodies, of course, quite rules out the diagnosis of epidemic encephalitis.

2. Other Parts of the Nervous System

Sympathetic ganglia Chachina (1926) reported that cellular infiltration, especially around vessels, and degeneration of neurons might be found (see also Marinesco and Draganesco, 1932)

Peripheral nerves Changes in the nerves connected with the site of the bite take the form of congestion and cellular infiltration, even at a distance from the wound *(see Marinesco and Draganesco, 1932) Giant cells may be found in the nerve (see,* e g, Nepveu, 1872, Dawydowski and Dwijkoff, 1928) Manouélian (1936 *b, d*) has reported that the sensory nerve filaments of the trigeminal in the face may show characteristic lesions Thus, Negri bodies occur in the nerve cells (endoneurocytes) which are found at intervals in the nerves Further, these cells may show degenerative changes and Van Gehuchten and Nelis lesions.

3. The Remainder of the Body

Salivary glands Changes in the submaxillary, parotid, and other glands have been reported (see Nepveu, 1872, Babès and Jonnesco, 1909 *a*) The acini are usually dilated and filled *with granular debris* The vessels and ducts are surrounded by a cellular infiltration consisting of fibroblasts, lymphocytes, and plasma cells

Kidneys The kidneys may show hyperemia and the tubules cloudy swelling and epithelial desquamation (Babès and Jonnesco, *1909 c*)

Adrenals The medulla may be infiltrated with mononuclears, especially around neurons (Marinesco, 1909)

Spleen The spleen may show hypertrophic and hemorrhagic or hyperemic follicles, with some central necrosis (Babès and Jonnesco, *1909 b*)

Pancreas The pancreas may present some epithelial desquamation of the excretory canals, and a pericanalicular infiltration (Babès and Jonnesco, *1909 a*)

neurofibrillary hypertrophy may be observed, particularly in cells of the spinal ganglia; the neurofibrils become hypertrophied, coalescent, and simplified.

Many degenerate nerve cells throughout the central nervous system, especially in the cord and spinal ganglia, are surrounded by leukocytes (see below, Babès nodules and Van Gehuchten and Nelis lesions), when the cell is completely destroyed neuronophagia occurs Negri bodies may be found in some of the less damaged cells (*vide infra*).

Inflammatory lesions. There is usually a well-marked leukocytic infiltration, diffuse and perivascular, in the spinal ganglia, cord (especially the gray matter), bulb and protuberances, and cerebellar and cerebral cortices. The infiltrating cells consist of lymphocytes, with a few plasma cells and polymorphs Thrombosis may occur in the vessels in the affected areas. Neuroglial reaction is usually present, especially in the region of the substantia nigra The astrocytes are mainly involved although the oligodendroglia react also, more particularly in the cord.

Babès nodules. These characteristic lesions of rabies, first described by Babès (see 1892 and 1912 *a*), have been demonstrated repeatedly by later workers (e g, Van Gehuchten and Nelis, 1900 *a*, *b*, Marinesco, 1909, Marie and Chatelin, 1919, Lowenberg, 1928, Bassoe and Grinker, 1930; Schukru-Aksel, 1934, 1935–6).

The lesions occur mainly in the cord and bulb where nerve cells are found to be surrounded by mononuclear phagocytic cells In the severest lesions neuronophagia takes place. The lesions are not in any way specific for rabies, of course, being merely the usual reaction of the leukocytic cells and microglia to degenerate neurons.

Van Gehuchten and Nelis lesions. Changes in the spinal ganglia were probably first noted in the latter half of last century. Thus, Nepveu (1872) recorded changes in the spinal ganglia of the affected side, he found that the ganglion cells were often surrounded and separated by leukocytes. He suggested that some of these leukocytes were probably epithelioid cells from the capsule of the ganglion cells. Similar changes were fully described and elaborated by Van Gehuchten and Nelis in 1900 (*a*, *b*), and the lesions are now usually known by their names Other workers have confirmed the presence of these lesions (e g, França, 1901, Marinesco, 1909, 1910, Marie and Chatelin, 1919, Dawydowski and Dwijkoff, 1928, Manouélian, 1936 *a*) The lesions consist of a collection of round cell leukocytes around a more or [illegible] ronophagia in the severer grades of the [illegible] advanced stage of degeneration it ma[illegible] Van Gehuchten lesion, the neurofibrillary network of the cell (Manouélian, 1936 *a*) The lesions are thus seen to be similar in nature to Babès nodules. Herzog (1945) has drawn attention to the presence of lesions in the ganglion nodosum of the vagus.

Negri bodies Numerous authors have recorded the presence of these characteristic inclusion bodies in man The bodies are eosinophilic structures measuring up to about 10 μ They may show an internal structure with granules of chromatin-like material. They are usually found in more or less undamaged nerve cells in the brain, particularly in Ammon's horn (hippocampus) They occur also in other parts of the central nervous system including the cord They have been found in the suprarenal gland. These bodies are fully described in a special section (see Ch LXXVI)

Having now studied the various individual changes that may occur, it remains to discuss their distribution in the central nervous system.

Meninges A slight degree of pial leukocytic infiltration, mainly perivascular, may occur, but quite often the meninges are normal. In other cases hyperemia may be present Lowenberg (1928) reported a case of an acute meningitis, definitely rabic in nature (see also Durand, 1941)

The cord The naked-eye lesions are usually those of congestion and some softening Microscopically a variety of lesions occurs Thus there is an infiltration

only 1 contracted the disease (McKendrick, 1940) showing that man to man transfer is very rare.

Animals which may transmit rabies to man.

Dogs. The most common reservoir of rabic infection throughout the world is in canines. The virus is spread amongst them by the bites of rabid members of the community. The canine virus has maintained the properties of street virus for probably over 2,000 years, although individual strains may differ slightly from each other in their characters. Canine rabies may sometimes exist in a locality without apparently giving rise to human cases (see, e.g., Bouffard, 1912, Blanchard and Lefrou, 1912).

In parts of Africa canine rabies is found, and this is occasionally transmissible to man. This infection was probably imported from Europe or elsewhere at some period and is quite distinct from another indigenous rabies, *oulou fato* or "mad dog" disease (see Heckenroth, 1918, Remlinger and Curasson, 1924, Hudson, 1944). *Oulou fato* is of definitely rabic nature and the virus has been quite thoroughly studied (see p. 812), it occurs in French West Africa, Senegal, and the Sudan. The affected dogs become paralyzed, and tend to segregate themselves, thus there is little opportunity for biting man. Human infection may, however, arise, and Nicolau, Mathis, and Constantinesco (1933) have isolated a strain.

The incubation period in dogs naturally infected is from 3–7 weeks, but may extend to somewhat over 6 months. The animal alters in disposition and shortly develops furious rabies (see p. 819). Pariah dogs are more likely to bite human beings than are domestic dogs. The dog is only infective if rabies virus is being excreted in the saliva, and it appears that in only about 50 per cent. of cases can virus be demonstrated in the submaxillary glands (Webster, 1942). Virus reaches the glands by passage along nerve trunks. The animal is probably infective for a day or so before clinical symptoms appear.

Cats. These animals are occasionally responsible for human cases of rabies (see, e.g., Remlinger and Bailly, 1930*c*, Wright and Gosden, 1946).

Wolves. Wolves are mainly concerned with the dissemination of rabies in Russia, Balkan, and Mid-European countries, and to some extent in France. The bites are usually very severe and energetic antirabies treatment is required.

Coyotes. Coyotes are responsible for the spread of rabies in California (Ledfors and Seiler, 1938).

Jackals. Jackals are common disseminators of rabies in India, as Kasauli statistics show, the bites usually being serious. They are responsible for about 30 per cent. of cases of rabies in India (Webster, 1944). They may also cause rabies in Northern Rhodesia (see Du Toit, 1936).

Skunks. In North America rabies may be contracted from the bite of a rabid skunk.

Viverridae. Animals of the mongoose family are being increasingly incriminated as transmitters of rabies. In India a number of bites has been inflicted by rabid mongooses. Thus at Kasauli from 1922 to 1933 there were over 30 such cases (see Grewal, 1932, 1933, Abbasi, 1943).

This family is probably of main importance, however, in South Africa, where the following members of the *Viverridae* may transmit human rabies. *Cynictis penicillata* (yellow mongoose), *Geneta felina* (genet cat), *Felis ocreata* and *nigripes*, *Suricata suricatta* (suricate), *Myonax pulverulentus* (pepper and salt meercat), and *Geosciurus capensis*. Interesting papers have appeared on this subject by South African writers (Thomas and Neitz, 1935–6, Du Toit, 1936, *Report*, 1936, Snyman and Thomas, 1938, Snyman, 1940).

Badgers and foxes. Rabies may follow the bite of rabid badgers and foxes (see, e.g., Lentze, 1931, Thomas and Neitz, 1935–6). There has been a number of out-

FIRST INTERNATIONAL CONFERENCE ON RABIES

A conference on rabies was held in Paris in April 1927, at *L'Institut Pasteur*, and was attended by the majority of leading rabies experts from all parts of the world, representing 26 countries Papers were read to the conference, and questionnaires previously sent out to antirabies institutes were considered. The official reports of the conference were compiled by MM. Marie, Remlinger, and Vallée. These have been published independently by the League of Nations (Marie, 1927 *b*, Remlinger, 1927 *b*, *c*; Vallée, 1927) and as a special supplement to the *Annales de l'Institut Pasteur* for 1927.

The conference adopted a number of resolutions which should be carefully studied, representing as they did the considered opinion of the world's leading authorities on the disease at that time.

EPIDEMIOLOGY

Geographical Distribution

There is no part of the world in which rabies may not occur. Thus, it exists in the northern regions such as Greenland and Iceland, temperate regions such as France, Germany, and other European countries, the United States and Canada, subtropical regions such as the Mediterranean littoral, tropical lands such as India, and the Far East.

With regard to Great Britain, in 1884 the incidence of rabies increased in London and the home counties, and in 1885 there were some 27 human deaths. Muzzling and surveillance of dogs were instituted with the result that by 1887 there were virtually no cases Great interest was taken in an outbreak of rabies among the deer in Richmond Park in 1886–7 (see Editorial, *Nature*, 1887–8), also one in Suffolk (Adami, 1889). From the Richmond Park outbreak the virus was isolated, on rabbit injection, by Cope and Horsley (1888).

After 1891 the muzzling laws were slackened or given little attention, and by 1895 there were again numerous cases of the disease. Reinforcement of the laws lessened the number of cases again, and from 1901 to 1918 there were no further cases in England After World War I came another outbreak, but muzzling soon brought this to an end, and since that time the disease has been virtually unknown In fact, since 1898 there have been only 2 deaths from rabies in England and Wales (*Memorandum*, 1944)

In America human cases occur sporadically, and a comparatively small number of deaths (under 100) occurs year by year Canine rabies is very common in some states (see Blatt *et al*, 1938, Denison and Dowling, 1939, Webster, 1942, *Publ Hlth. Rep*., 1947) On the European continent the disease is common, as it is in Algeria, Morocco, Tunisia, and other parts of North Africa In parts of Africa an indigenous form of rabies affects dogs (*oulou fato*) which is rarely transmissible to man (see pp 801 and 812 *Oulou fato* is not the common type of rabies of French West Africa, where strains of virus are usually of full virulence (Lépine *et al*, 1939) In South Africa the disease is not prevalent, but a few cases occur from time to time, usually following the bites of animals of the mongoose family (meercats, etc, see p. 801) The disease is very prevalent in India, Indo-China, and the Far East

Method of Spread of Rabies

The vast majority of cases occurs following the bite of a rabid dog or other animal, and a full list of animals which have transmitted rabies to man will shortly be given. In certain cases, however, the animal may not actually bite, but only scratch or claw the skin In all such cases rabies may follow, though only comparatively rarely Cases have occurred where a child has bitten a parent, necessitating anti-rabies treatment (see Pampoukis, 1900), of 8,581 persons in contact with rabies

are discussed on p 830.) Following local treatment, a course of antirabies treatment should be instituted forthwith (see Ch LXXVIII).

General Measures for the Control of Rabies

The control of rabies on a large scale is a complicated matter and involves attention to a considerable number of different points. Each country has varying rules and regulations and there is, as yet, no international agreement as to the best method of limiting the spread of the disease The procedure followed in Great Britain during the 1918 outbreak has been described (*Memorandum*, 1944) The reader is also referred to the valuable official publication of the Government of India (Webster, 1944), and the paper of Tierkel (1948) on the plans of the United States Public Health Service.

(*A*) *Destruction of animals* A number of countries enforce destruction of all rabid animals and those animals bitten by them. The following regulations, as used in Palestine (Stuart and Krikorian, 1925), are given as a model

1 Every rabid animal to be destroyed,
2 Animals bitten by rabid animals to be dealt with as follows
   (*a*) monkeys, dogs, cats, to be destroyed,
   (*b*) camels, bulls, cows, calves, sheep, goats to be slaughtered, the carcasses may be sold for food,
   (*c*) valuable animals to be destroyed, isolated, or given antirabies treatment
3 Every animal bitten by a suspectedly rabid animal to be destroyed or isolated Dogs in contact with other dogs, suspectedly rabid, should be destroyed or isolated
4 All animals that have bitten a human being are to be isolated and closely watched for at least 10 days, from the point of view of treatment, it is most important to know whether the person has been bitten by a genuinely rabid animal or not
5 Stray dogs and jackals should be destroyed

(*B*) *Muzzling*. Muzzling always markedly reduces the number of cases of rabies spread by infected dogs (for an illustrative chart, see Harvey and McKendrick, 1930). The order must be enforced strictly and backed up by measures to deal with stray dogs In New York, leashing has been allowed as an alternative to the more irksome muzzling (see Olesen, 1935).

(*C*) *Quarantine* The practice in many island countries is to quarantine for some months all dogs entering the island This measure is usually remarkably effective An interesting example of what may happen when rabies is introduced into a small island previously free was afforded in the case of Madeira in 1894 (Goldschmidt, 1894) The disease spread rapidly among dogs, goats, and cats, and there were some human cases It was suspected that some dog imported to the island must have been incubating rabies on arrival There have been similar outbreaks recently, for instance in Corsica, traced to the entry of soldiers' pet dogs (Lépine, 1946)

In Great Britain at the present day, strict quarantine is imposed on dogs imported into the country, 6 months observation being enforced Galloway (1945) reports that in 21 years 16 cases of rabies have developed in quarantined dogs, and the 6 month period is fully justified

(*D*) *Education of the public* In any area where rabies is endemic an effort should be made to teach the public the exact epidemiology of the disease They should be encouraged not to keep dogs, but if they must, muzzling or leashing should be insisted on The public should be trained to report all dog bites to the health authority In this way the person bitten can be subjected to antirabies treatment at once, and the offending animal removed for competent veterinary exami-

breaks of rabies in foxes in the southern states of the United States (Sellers, 1941; Johnson, 1945; Public Health Reports, 1947).

In New York State in 1946 there were 308 reported cases in foxes, and 440 in cows, the fox rather than the dog appears to be the central figure in rabies epidemiology, with cattle being infected by the bites of foxes (Korns and Zeissig, 1948).

Mice. Remlinger (1905 *c*) recorded a case following a mouse bite.

Birds. Rabid birds may (rarely) attack human beings, necessitating antirabies treatment (see Kraus, Gerlach, and Schweinburg, 1926, Remlinger and Bailly, 1929 *a*).

Other animals Harvey and McKendrick (1923) give the following list of animals which have been known to bite when rabid. horse, ox, buffalo, hyena, panther, camel, goat, deer, elephant, bear. The rabid ass and calf may also bite, but it must be emphasized, from the practical point of view, that ruminants and solipeds are practically never concerned in the causation of human rabies. For example, of 26,802 persons bitten by solipeds and ruminants, and subjected to antirabies treatment, only 3 developed rabies (McKendrick, 1940) Smith *et al* (1938) reported that for the past 30 years no death from hydrophobia was recorded from the Kasauli Institute and its out-stations, from bites of horses, cows, donkeys, or buffaloes

Denison and Leach (1940) examined 500 rats in Alabama, but failed to isolate virus by mouse inoculation.

The infectivity of rabid animals.

In the great majority of cases the infection is transmitted by means of the saliva of the biting animal. It has often been demonstrated that the saliva is infective during the period of the declared disease (see p. 826) Further, a number of observations has shown that the saliva of dogs may be infective several days before the appearance of symptoms of rabies (see p 827). Therefore, in countries where rabies occurs, any dog bite should be regarded as possibly that of an infective animal

Rabies developing apart from a bite must be considered as exceptional, although there have been a few such observations (see above).

According to some observations in America (see Webster, 1937), it is probable that dogs may carry the virus in the central nervous system without showing typical symptoms of rabies Thus the virus has been isolated (by mouse inoculation) from dogs showing fits and other indefinite, not characteristically rabic, symptoms. There is no evidence, however, that dogs can act as symptomless carriers (Johnson, 1943)

Personal Prophylaxis

The wound should be encouraged to bleed According to Mackie (1928) it is advantageous to wash out the wound with acriflavine, and then pack with gauze soaked in the antiseptic Prompt cauterization with a thermocautery, fuming nitric acid, or phenol is usually recommended (Ekstrom, 1830), but there is little evidence that such drastic agents are more effective than milder antiseptics such as iodine or even simple soap washing (Shaughnessy and Zichis, 1943) The general opinion is that cauterization has a definite value, but our attempts to obtain recent accurate figures to support this statement from various Pasteur Institutes have proved fruitless Some years ago Harvey and McKendrick (1923) found that efficient cauterization lowered the mortality rate in the ratio of 4 3 Experimentally it has been shown that cauterization of infected animal wounds, although usually effective up to half an hour after the infliction of the injury, may fail, even within 5 minutes (Babès and Talasescu, 1894) (The effects of cauterization on experimental rabies

of brain may be removed and pressed firmly down onto the slide by a coverslip. (Instead of removing the bone with bone cutters, it is safer to smash it with a heavy blow, before the skin is reflected. Pieces of bone may then be picked off, and the brain exposed.)

Microscopical examination.

1. *Wet films.* The debris on the lancet used to scrape the hippocampus is floated out in dilute acetic acid. The preparation is then examined wet and unstained for the characteristic inclusions (see Negri-Luzzani, 1913).

2. *Stained films.* Scrapings from the hippocampus may be stained by Giemsa's stain as a film preparation. Webster (1944) prefers a modified Van Gieson stain as follows: the gray matter is crushed and spread on a slide by pressure under a coverslip. Without drying, the film is fixed in methyl alcohol for 2 minutes. Then stain for 5 minutes with the following stain freshly mixed. (*a*) 0.3 c.c. saturated alcoholic basic fuchsin; (*b*) 2.0 c.c. saturated alcoholic methylene blue, (*c*) 30 c.c. aq. dest. Then wash rapidly in water, and dry. In such films the Negri bodies are generally found lying free. Sellers' method is popular in America (1927).

3. *Preparation of sections.* Small pieces of the horn are fixed for 2 to 4 hours in formol saline, spirit, or Zenker's solution. The tissue is then taken to paraffin in the usual way as rapidly as possible. Sections are cut so that the face is a frontal section of the whole horn, they should be stained by Mann, Hamilton, Lépine or

[illegible] er cent., 90 per
cent., and absolute alcohols, acetone, xylol, 2 changes of paraffin. After blocking and sectioning, Van Gieson's stain (as above) is applied for 3 minutes with the usual technique applicable to paraffin sections.

In addition to the search for Negri bodies in Ammon's horn, it is well to have sections made from various other parts of the central nervous system. These should be subjected to a general histological examination as well as searched for Negri bodies. Babès lesions are present in a [illegible]

nation. As found necessary, it may be destroyed forthwith, isolated, or returned to its owner to be reexamined later (see, e.g., Olesen, 1935).

(*E*) *Prophylactic vaccination of animals* This subject is discussed in Ch. LXXVII.

(*F*) An interesting account of the very varied measures to control rabies followed in most of the states of America and the provinces of Canada will be found in *Public Health Reports*, 1947, *62*, 1215. In brief, the measures recommended include. (1) The introduction of a national plan for rabies eradication (2) Regulation of interstate transport of susceptible animals (3) Regulations governing the importation of susceptible animals from abroad to be administered by the Public Health Service. (4) All cases of rabies, human and animal, to be reported. (5) Annual licensing of dogs to be introduced. (6) In urban areas, the granting of a license to be made contingent on vaccination. (7) Vaccination of dogs by annual injection (see p. 848) (8) The establishment of quarantine during outbreaks of rabies in dogs, proper disposition of rabid and suspectedly rabid dogs, destruction or supervised detention for not less than 3 months of dogs known to have been bitten by or exposed to rabid animals, and the impounding and disposal of all stray dogs.

LABORATORY DIAGNOSIS

Human Rabies

The laboratory examination of persons dead as a result of suspected rabies involves 2 lines of approach First, the hippocampus should be dissected out, films made and suitably stained (*vide infra*), and the remainder fixed prior to histological examination for Negri bodies (see Ch LXXVI). Other portions of the central nervous system also should be examined histologically. Secondly, a suspension of the bulb should be made and injected intracerebrally or subdurally in rabbits It is as well to prepare suspensions from several areas of the central nervous system, as the distribution of virus may be patchy (Koch, 1929) If a virus agent is isolated, it should be tested for its effect by other routes of injection, and on other animals Mice may also be injected and Negri bodies searched for in their brains (Webster, 1936, 1937, *vide infra*). Tissue cultures may be inoculated (Plotz and Reagan, 1942) It is always worth while considering the possibility of rabies in any obscure nervous case (Schaeffer and Leider, 1941–2).

Canine Rabies *

When a person has been bitten by a dog or other animal, steps should always be taken to discover if the animal is actually rabid or not If living, it should be isolated to see if rabies develops, if dead, the head of the dog should be sent to the laboratory packed in ice, or failing this in glycerol or salt If neither of these substances is available, it should be remembered that Negri bodies resist putrefaction for some time Various methods are in use for the examination of the head, but they mostly resemble the method of Negri-Luzzani (1913)

The skin is slit in the middle line from the occiput forwards to the muzzle, and the skin flaps are reflected to the level of the ears The exposed skull bone is then removed with a suitable cutting instrument The dura is cut and the cerebral hemispheres exposed The brain is removed (or it may be left *in situ*) and the superficial parts of the hemispheres sliced away horizontally, down to the level of the corpus callosum A dissection is then made into the temporal portion of the lateral ventricle to expose Ammon's horn (hippocampus) The horn is dissected out and cut perpendicularly with a razor, then a lancet is scraped fairly deeply over the cut surface and the scrapings examined microscopically Alternatively, a small piece

* In Great Britain specimens may be sent to the Veterinary Laboratory of the Ministry of Agriculture and Fisheries, Weybridge

CHAPTER LXXIV

TRINIDAD RABIES

Trinidad rabies was first brought to general notice by an official report (*Report*, 1931)[1] and by a paper of Hurst and Pawan (1931). The latter reported 17 cases (all fatal) of acute ascending myelitis The patients came from Siparia in S.W. Trinidad, were natives, and mostly school children. Infection by the bite of vampire bats was suspected, as almost all cases had a definite history of having been bitten on the feet or lower limbs. Pawan (1936 *a*) reported that at that time there had been over 50 human cases, all of whom died. Later (1939) he reported the occurrence of 73 cases to date.

CLINICAL FEATURES

The clinical features have been described from time to time (Hurst and Pawan, 1931, 1932; De Verteuil and Urich, 1935–6, Pawan, 1936 *a*).

Incubation period. Symptoms usually develop from 3 to 4 weeks after the bite of the bat

Onset The onset is characteristically sudden The patient is febrile and often has a headache The bitten foot or leg usually feels burning and tingling, and may actually be paresed at the onset of the disease.

Course. After these prodromal symptoms, which may last for 1 to 4 days, the muscular weakness progresses to complete paralysis of the leg with anesthesia and loss of reflexes. The trunk muscles are soon involved also, and the paralysis spreads to involve the arms and finally the bulbar nerves. The temperature may be raised Excessive salivation usually occurs, but only in the terminal stages are there hydrophobic symptoms

PATHOLOGY

The pathological features have been described in detail by Hurst and Pawan (1931, 1932). Naked-eye, the cord appears congested and soft, especially in the cervical and dorsal regions. The brain also is congested The heart may show [illegible] re is [illegible] s of [illegible] de- [illegible] ears [illegible] tion of the sheath

EPIDEMIOLOGY

The disease tends to occur in small localized epidemics which last from 1 to 10 weeks, the number of cases in any one epidemic has varied from 13 to 43 (De Verteuil and Urich, 1935–6). As regards seasonal incidence, 64 per cent. of cases have occurred from May to August, in the rainy season (De Verteuil and Urich). Investigations have conclusively proved the disease to be spread by the bat (see, e.g., Hurst and Pawan, 1931, 1932; Metivier, 1935; De Verteuil and Urich, 1935–6, Pawan, 1936 *a*, *b*, 1937).

[1] References are appended at the conclusion of Ch LXXIX, p. 857 et seq

examined for Negri bodies. The remaining 3 animals are kept for a month to see if rabies develops. Animals may also be injected in the tail (Jonnesco, 1934 *a*).

Tissue cultures also may be inoculated

To obtain a positive diagnosis in the largest possible number of cases, it is essential to examine the canine material for Negri bodies as well as attempting to isolate virus by animal inoculation. A significant number of specimens in which Negri bodies cannot be found will prove positive on animal inoculation, and to a lesser extent some specimens negative by animal inoculation contain Negri bodies (Damon and Sellers, 1941–2, 1942).

In the cord, changes occurred in the lumbar portion, where nerve cell degener-

in the lumbosacral portion

The lumbar ganglia showed the more severe inflammatory infiltration on the inoculated side, but the nerve cell degeneration was equal on the 2 sides

Negri bodies were found regularly. They measured from 2 μ to 15 μ or rarely 25 μ, and occurred more profusely in Ammon's horn than elsewhere.

Hurst and Pawan made a comparison of these histological findings with those produced by *virus fixe* Following intracerebral inoculation with *virus fixe* the changes were more distinctly inflammatory. The lesions of *virus fixe* were as severe in the basal nuclei as in the cortex, this did not obtain with Trinidad virus, where the basal nuclei showed less change than the cortex. The changes in the cerebellum also were severer with *virus fixe*.

Rabbits Rabbits can also be infected with Trinidad virus, by intracerebral injection (Hurst and Pawan, 1931, 1932, Andrews, 1933) The symptoms are those of paralytic rabies, although Remlinger and Bailly (1932 *a*) noted a fairly prolonged stage of motor excitement prior to paralysis Histologically the cerebrum showed meningeal cellular infiltration, perivascular cuffing, and microgliosis (Hurst and Pawan, 1932) The nerve cells showed all stages of degeneration The brain stem showed m[illegible]

bellum sho[illegible]

tion, and n[illegible]

Pawan [illegible]

Rabbits w[illegible]

bodies were not found.

Guinea-pigs. Andrews (1933) has reported that these animals are more susceptible to Trinidad virus than to ordinary rabies virus Apparently after injection they may develop the furious form of rabies (Remlinger and Bailly, 1932 *a*)

Dogs After intracerebral injection the animals develop paralysis of the posterior limbs, and some may bite (Remlinger and Bailly, 1932 *a*)

Other animals. Remlinger and Bailly (1932 *a*) reported that the virus could be transmitted to the following animals cat, buzzard, rat, mouse, *Meriones shawi*, gerbille, and hen

Antigenic Structure

Rabbits immunized by killed *virus fixe* were protected against a subsequent injection of Trinidad virus On the other hand, Trinidad virus did not confer much resistance against a subsequent injection of *virus fixe* (Hurst and Pawan, 1932; Pawan, 1936 *a*)

Trinidad Rabies in Cattle

In 1925, cattle near Port-of-Spain were found to be affected by an unusual disease, dying of a form of bulbar paralysis with ataxia, salivation, and constipation. By 1926 it had spread farther west to Diego Martin, and by 1935 all parts of the colony were infected (Metivier, 1935) By 1936 about 2,000 animals had died from the disease (Pawan, 1936 *a*)

The animals most commonly involved, apart from cattle, are horses, mules, donkeys, goats, sheep, and pigs By 1930 to 1931 the disease had assumed a somewhat *different* clinical form from its original, now it is more of an acute ascending myelitis than a bulbar paralysis The animals salivate, stop grazing, and are ataxic, by the 3rd day of the illness they lie down and usually die within a day or two.

It was realized that the disease closely resembled the paralytic rabies of bovines in

The Rôle of the Bat

Species of bat incriminated. The main vector of Trinidad rabies is *Desmodus rotundus murinus* (Wagner, 1840) This bat is a blood-lapper, and its habits have been described by various writers (in particular by De Verteuil and Urich, 1935–6). The animal measures about 13 inches from wing to wing, and has very sharp teeth with which it pierces the skin; it prefers to bite dark skin to pale. The blood oozes out and is caught in the bat's mouth The sole food of the desmodus bat is blood, bovine or human, its normal food is bovine blood, and it only attacks men if animals are shut away. It has often been noticed that stabling of live stock results in an outbreak of human cases. The bat bites only in the dark, while during the day it retires to sleeping places in caves, trees, and under bridges It deposits a characteristic tarry excrement

Another species of bat—the fruit-eating bat, *Artibeus planirostris trinitatis*—has been found to carry the virus of rabies. Although this animal does not attack man it may act as a reservoir of infection for a community of desmodus bats (De Verteuil and Urich, 1935–6)

Natural rabies in bats. Various Trinidad observers have noted that desmodus bats may develop clinical manifestations of furious rabies, and frequently fight with each other. The saliva and salivary glands have been found to be infective (Pawan, 1936 *a*), and there is no question that the disease is spread from bat to bat, as well as to man or animals, by bite

Probably bats may harbor the virus without showing any obvious manifestations of infection (Pawan, 1936 *b*).

Fruit-eating (artibeus) bats may fight with desmodus bats and transmit the infection to them, but artibeus bats do not attack man

Infectivity of the bat Numerous observations have been carried out on bats caught in Trinidad by Pawan (see 1936 *a*). The virus of rabies has been isolated, by inoculation of monkeys and calves, from the brains of both desmodus and artibeus bats infected under natural conditions. Also, Negri bodies have been found in approximately 4 per cent. of bats—mainly desmodus, but sometimes artibeus.

Preventive measures involve burning bright lights and erecting nets to keep away the bats, but these procedures are not very effective. More hope is to be expected from the intensive campaign of bat destruction that is being practiced on the island

PROPERTIES OF TRINIDAD RABIES VIRUS

Animal Inoculation Experiments

Bats. Bats can be inoculated experimentally (intracerebrally) and may develop furious rabies, paralytic rabies, or may harbor the virus without developing symptoms (Pawan, 1936 *b*).

Monkeys The disease may be transmitted to monkeys by intracerebral injection (Hurst and Pawan, 1931, 1932) After 7 to 9 days the animals become aggressive, have violent muscular spasms or convulsions, and die within about 12 hours Intrasciatic injection also secures infection

The histological features have been described *in extenso* by Hurst and Pawan (1932) Thus, in group 1 the inflammatory changes were only slight. Microglial foci, nerve cell degeneration, and perivascular infiltration might all be found in the cord and higher parts of the central nervous system The spinal, as well as gasserian and sympathetic, ganglia showed marked changes Many nerve cells were degenerate or actually necrotic, and often replaced by capsular cells, there was also a diffuse cellular infiltration. In group 2 inflammation was more marked The cerebrum showed some meningeal infiltration and perivascular cuffing Microglial foci were well developed, consisting of proliferated microglial cells and a few lymphocytes At the periphery infiltration was more diffuse

CHAPTER LXXV

THE RABIES VIRUS

STRAINS OF RABIES VIRUS

A. Street Virus

THE strain of rabies virus found in nature, in man, and animals, is known as street virus, or *virus de rage de rue*. When street virus is passaged through animals by intracranial injection, it eventually becomes modified in its properties, and is then known as fixed virus or *virus fixe*.

Strains of street virus vary greatly in the rapidity with which fixation occurs, as represented by the standardization of the incubation period and the increasing rarity with which Negri bodies develop

Stuart and Krikorian (1931)[1] have suggested that street viruses may be classified into various groups.

1. These strains show short incubation periods *de novo* and are true *virus de rue renforcé* strains
2. (*a*) Strains of high virulence in which complete fixation occurs after a few passages.
   (*b*) Ordinary strains of street virus in which fixation occurs in about 50 passages
3. Strains of low virulence where fixation does not occur even after prolonged passage.

1. *Virus de rue renforcé.*

This term is applied to certain strains of street virus of unusual virulence isolated from various sources (Calabrese, 1896, Remlinger, 1926 *b*, Harvey and Acton, 1922–3, Alivisatos, 1926, Calderini, 1928, Téodorasco, 1928, Koch, 1929, Jonesco, 1930 *a*, Stuart and Krikorian, 1931, and others, *vide infra*).

General characters

Incubation period in man It has been suggested that the shortness of the incubation period in various human cases is due to infection with one of these *renforcé* strains (see, e g, Alivisatos, 1926, Bablet and Joyeux, 1930, Genevray and Dodero, 1934) Proca and Bobes (1940), however, on the basis of an extensive experience concluded that there was no parallel between the incubation period in untreated persons and the incubation period in rabbits inoculated intracerebrally with brain suspensions of these patients

Animal inoculation. In rabbits, after subdural inoculation, the incubation period is much shorter than the usual 15 or more days characteristic of street virus. Symptoms of paralytic rabies usually develop within 10 days of infection, and possibly even after about 3 to 5 days. These strains may prove of normal virulence for the guinea-pig (Remlinger, 1925 *b*) Negri bodies are usually completely absent. Fixation occurs in rabbits after very few passages, perhaps only one or two (Jonnesco, 1938 *b*).

Properties of individual strains.

A large number of strains falling into group 1 (Stuart and Krikorian) has been isolated, and the following are the best known

(*a*) *Tangier B strain*, (*b*) *Puymyrol*; (*c*) *Soucy* (see Stuart and Krikorian).

[1] References are appended at the conclusion of Ch LXXIX, p 887 et seq

South America, and it was soon found that it was spread by the vampire bat *Desmodus rotundus* As the coast of South America is only 10 miles from Trinidad, it is possible that in the first place infected bats flew or were carried by ship.

Negri bodies can be found in the central nervous system of the paralyzed animals, and rabies virus can be obtained from the central nervous system or saliva by injection of monkeys, rabbits, or other susceptible animals (Hurst and Pawan, 1932; Pawan, 1937) These facts definitely establish the rabic nature of the infection.

(Q

The cerebrum showed some meningeal round cell infiltration, and perivascular cuffing was noted in the gray matter, and to a lesser degree in the subcortical white matter. Microglial proliferation occurred in the gray matter. There was some satellitosis, but no neuronophagia.

The cerebellum showed some degeneration of Purkinje cells, microgliosis, and the presence of Negri bodies. The pons showed much perivascular cuffing, microgliosis, and nerve cell degeneration. The cord showed rather patchy changes, but microgliosis, perivascular cuffing, nerve cell degeneration, and Negri bodies were all found.

South American Bovine Paralytic Rabies (mal de caderas)

For some years a paralytic disease of horses and cows, which is known locally as *mal de caderas,* has been prevalent in South America. Numerous papers have appeared on the subject (see, e g, Carini, 1911; Haupt and Rehaag, 1921, Rosenbusch, 1930, Remlinger and Bailly, 1931 *a*, Migone and Peña, 1932, Quiroga *et al*, 1932; Pawan, 1936 *a*, Molina, 1938, Everling, 1939) Those who are interested will find fuller references in the *Tropical Diseases Bulletin* and in the *Boletín* for 1936

The disease enjoys a wide distribution over the continent of South America, occurring in Santa Catharina (S Brazil), North Brazil, Paraguay, Argentine, British Guiana, Venezuela, Bolivia, and probably elsewhere

Horses and cows are most commonly affected and develop an ascending paralysis resulting in paraplegia The fatality rate is from 20 to 60 per cent. The disease is usually contracted at night, and animals in stables generally escape The infection is transmitted by blood-lapping (desmodus) bats, and the virus of rabies has been isolated from naturally infected bats

The rabic nature of the disease was first established by Haupt and Rehaag in 1921 Negri bodies occur in the brains of the affected bovines, and rabies virus can be isolated also by suitable animal inoculation The infection can be transmitted experimentally to bovines by injection of virus

In laboratory animals the symptoms are those of *virus fixe* Thus, Remlinger and Bailly (1931 *a*) found that rabbits, guinea-pigs, rats, mice, dogs, sheep, hedgehogs, jackals, and buzzards were all susceptible, and developed paralytic rabies

Mexican Derriengue

Johnson (1948) has described the main features of this fatal paralytic illness of cattle on the Pacific coast of Mexico, that may occur in the form of epizootics Rabies virus has been isolated from a cow and from vampire bats

authors (Remlinger and Curasson, 1924; Remlinger, 1926 *b*, Jadin, 1939). Further, a human st

Fixation

eventually

as passage

infectivity (as tested by dilutions) is increased approximately 40 times by fixation, *virus fixe* resists glycerol for 3 to 4 months whereas street virus only resists for 3 to 4 weeks.

By passage of a street strain of *oulou fato* through rabbits 2 different fixed strains were isolated, one having an incubation period of 8 to 10 days, the other 10 to 12 days (Nicolau, Mathis, and Constantinesco, 1932).

Animal inoculation. Rabbits injected subdurally with street virus die after about 18 days from paralytic rabies, often with a preliminary phase of excitation. Fixed virus produces a purely paralytic disease. Animals can also be infected with street virus by the dermal, muscular, corneal, sciatic routes, and by the posterior chamber of eye.

Guinea-pigs also die of paralytic rabies, from infection with both street or fixed viruses Monkeys, rats, mice, dogs, and hens can all be infected with *oulou fato* virus.

Pathology. The pathological features of infected animals do not differ from those usually found in experimental rabies.

Cross immunity tests have established the complete identity of *oulou fato* virus with classical strains of rabies virus.

B. Miscellaneous Strains

herpetic (Luger

was soon proved

virus was found to be

The histological pictur

tests detected no relationship between Koritschoner's virus and Doerr's or Levaditi's herpes strains, these tests showed, moreover, that Koritschoner's virus was identical with rabies virus (Takaki, 1926)

2. *Kobayashi's (1925) virus.* This strain was isolated from a case of Japanese encephalitis in 1924. Kobayashi himself realized that the strain was very similar to rabies The proof was completed by Cowdry (1927) by animal and cross immunity tests.

3 *DK virus* This strain, thought to be herpetic, was shown to be rabic by cross community reactions (Nicolau and Kopciowska, 1929)

4 *Virus ECK* (*Silberstein*) This virus was isolated from the brains of dogs operated on to produce Eck's fistula and its precise nature seems to be in some dispute, some claiming it to be a rabic strain (see Remlinger and Bailly, 1930 *i*)

5 The virus known as Moscow 2 appears to be a rabic strain (Howitt, 1941).

C. *Virus Fixe*

The process of fixation.

Street virus is usually fixed by passage intracranially through rabbits. With the progress of time, the usual 15 to 21 day incubation period of street virus becomes shorter and shorter until it eventually reaches 6 to 8 days (see, e.g., Pasteur, Chamberland, and Roux, 1884, Hoegyes, 1888, Celli and Marino-Zuco, 1892, de Blasi and Travalli, 1894)

As has been mentioned above, strains of street virus vary greatly in the ease with which they become fixed, some becoming so almost at once, other strains

(*d*) *Chisinau strain.* Remlinger and Bailly (1930*a, b*) reported on the properties of this Roumanian strain. The incubation period in rabbits was 7 to 8 days after subdural inoculation, and virus was also infective intramuscularly, subcutaneously, and intra-ocularly. The following other animals were infected: the dog, guinea-pig, cat, jackal, fowl, pigeon, and buzzard. Cross immunity tests (with fresh or etherized virus antigens) showed that the Roumanian strain was identical antigenically with the street virus of Tangier and with *virus fixe.*

(*e*) *Safad strain.* This strain of *virus renforcé* was isolated in Palestine from a human case bitten by a jackal (Stuart and Krikorian, 1931).

(*f*) *Jonnesco's (1932) strain.* Jonnesco (1932 *c, d*) isolated a strain of *virus de rue renforcé* from a rabid wolf. Inoculated intracerebrally in rabbits the incubation period was only 3 days, and in guinea-pigs 2 days Dogs and cocks were the only animals in which Negri bodies could be found. The strain was shown, by cross immunity tests, to be identical with ordinary street and fixed viruses.

(*g*) *Jonnesco's (1938 a, b) strains.* The same worker isolated 4 more strains from persons who died of rabies despite antirabies treatment. These strains were highly pathogenic to mice.

(*h*) *Bablet and Marneffe's (1932) strain.* This strain was isolated from a person who died in Hanoi in less than 20 days, although subjected to antirabies treatment. A strain of virus, killing rabbits in less than 8 days, was isolated from the bulb.

(*i*) *Pawan's (1938) strain.* This strain was isolated from a rabbit bitten by a desmodus bat. Rabbits were killed in 2 days and no Negri bodies could be demonstrated (see Ch. LXXIV)

(*j*) *Proca and Bobes' strains.* These workers reported on 389 strains of street virus and found that 40 per cent. had incubation periods in rabbits inoculated cerebrally of under 15 days.

2 (a) Strains ***(of virus renforcé).***

(*a*) *Gréen strain,* (*b*) *Tétuan strain;* (*c*) *Virus Tangerois-Martin;* all isolated from rabid dogs (see Remlinger, 1926 *b*).

(*d*) *Strain CN* from Bucharest (Levaditi, Lépine, and Schoen, 1929).

(*e*) *Odessa strain* This strain was isolated by Palawandow and Serebrennaja (1933) from the saliva of a patient bitten by a dog. In guinea-pigs inoculated subdurally, the usual incubation period was about 2 to 3 days, although somewhat variable. Fixation occurred after 29 passages.

In these strains (*a–e*) fixation usually takes 15 to 30 passages, when the incubation period becomes stabilized and Negri bodies no longer develop Apart from rapidity of fixation, the characters resemble those of ordinary street virus 2 (*b*) strains

(*f*) In a somewhat different category from the above strains are those of Trinidad rabies and *mal de caderas.* These strains form Negri bodies readily but, on animal inoculation, possess other characteristics of *renforcé* strains (see Ch. LXXIV).

2 (b) Strains.

This group contains the bulk of street viruses, and is the group generally referred to when one talks of "street virus" without additional qualification. The properties of ordinary street virus have been described in great detail in the literature, and many resemble those of fixed virus These characteristics are described below, and form the major part of this chapter

3. Strains of low virulence.

We shall describe in this section the virus of *oulou fato,* a strain of low virulence which can, however, usually be fixed after numerous passages. These strains from indigenous mad-dog disease of North Africa have been investigated by certain

2. Negri bodies are found regularly in street virus infections but only under special circumstances with fixed virus (see Ch. LXXVI). Lentz bodies are only found with *virus fixe*.
3. The rate of multiplication of street virus in the central nervous system is said to be less rapid than is the case with *virus fixe*. Fixed virus usually appears to be the more infective when tested in serial dilutions, thus, certain strains of *virus fixe* have an infective titer of 1/500,000 to 1/900,000, while [illegible] 2,000 to 1/100,000.
4. [illegible] lent as the white, [illegible] virulent (Harvey and Acton, 1922–3).
5. Fixed virus has an attenuated affinity for tissues other than the central nervous system. Injection of fixed virus subcutaneously usually fails to infect dogs, although rabbits are more susceptible
6. Dogs infected with street virus develop furious symptoms, whereas with fixed virus, paralytic rabies is noted
7. Guinea-pigs infected with fixed virus usually develop paralytic rabies, but with street virus some other manifestation occurs (see p 822).
8. Fixed virus is of low virulence for man, although probably not completely harmless (see neuroparalytic accidents, Ch. LXXIX).
9. When *septinévrite* is induced by intraneural or intracerebral injection, fixed virus does not disseminate throughout the nerves nearly so regularly as does street virus.
10. Remlinger and Bailly (1943 *b*) have made the suggestion that street virus may be considered as a "rough" or less virulent variant of fixed or "smooth" virus.

Simultaneous infection with fixed and street viruses.

Marie (1930) injected rabbits intracerebrally with a mixture of street and fixed viruses, and found that half died with the characteristics of one infection and half with the other. Plantureux (1933), on the other hand, found that rabbits so injected usually died from fixed virus infection (see also Bozzelli, 1935).

Injected intra-ocularly, the mixture produced symptoms after 10 to 15 days, whereas *virus fixe* on its own was noninfective, and street virus did not cause symptoms for 18 to 27 days Guinea-pigs injected with mixtures of the two strains died from *virus fixe* infection (Marie, 1930).

Special strains of *virus fixe*.

Most of the properties of the ordinary strains of *virus fixe* are similar to those of street virus and are fully described below. In addition to the ordinary strains of *virus fixe*, however, some with unusual properties have been described, and these will first be mentioned.

1 *Sassari fixed virus.* This virus, maintained at the Sassari Anti-rabies Institute for many years, has been used in the manufacture of Fermi's vaccine. Its properties differ from the usual *virus fixe* strains in certain respects and have been studied in particular by Fermi (1907), Repetto (1908), and Lépine and Sautter (1936) Thus, Negri bodies are readily developed in rabbits on intracerebral injection, rats are regularly killed on subcutaneous injection, and mice are very susceptible to the virus even by ingestion.

2 *Remlinger and Bailly's* (1935 d) *strain.* These authors investigated a strain of *virus fixe* in use in an institute where there appeared to be an unusual number of neuroparalytic accidents occurring They found that it was unduly resistant to desiccation, even 17- to 18-day cords proving infective. Further, a 3-day cord remained virulent in glycerol for 44 days, and in ether for 280 hours.

3. *Brussels strain* Le Fèvre de Arric and Tchang Kouo-Ngen (1924) compared the properties of the Brussels and Paris strains of *virus fixe*, and found that the

after about 20 passages, the average being about 50 passages, and some strains may never become fixed at all. Fixation may also be carried out by passage through dogs, monkeys, guinea-pigs, or cats. An unusual occurrence was reported by Helman (1888), who attempted to fix a *strain of street virus by rabbit subdural* passage. Despite 60 passages no fixation developed. With the 11th-passage brain, however, he initiated another parallel series of passages. This "branching-off" proved successful and fixation occurred with this line of virus.

The stability of *virus fixe*.

A number of attempts has been made to convert *virus fixe* back to street virus, and certain of these have been partially successful. Generally speaking, however, the properties of *virus fixe* are remarkably stable and alterations in behavior are very rarely observed. For instance, although an earlier report suggested that intracranial passage through dogs might somewhat alter the properties of *virus fixe* (Nicolle and Burnet, 1924), this was later denied (Nicolle and Balozet, 1932).

Passage of *virus fixe* through hedgehogs results in an increased virulence for the rabbit, the production of furious rabies in the dog, and the capacity of once more forming Negri bodies Another line of approach has been to treat *virus fixe* with chemical agents in an attempt to change its nature. Thus it has been reported that, by suspending *virus fixe* in bicarbonate of soda, furious rabies develops in animals instead of the usual paralytic symptoms (Remlinger and Bailly, 1936 *c*). Further, Jonnesco (1939 *a*), after storing fixed virus in glycerol for 144 days, found that, after inoculation into rabbits, symptoms were not produced until 16 days had elapsed, whereas previously the incubation period had been only 3 days. Negri bodies also occurred although they had not been produced by the strain before glycerolization. These changes, however, passed off with passage.

The method whereby most change has been produced in the characters of *virus fixe* is that of nerve passage. This work has been carried out mainly by continental workers (Kopciowska, 1935 *a*, *b*, Nicolau and Kopciowska, 1934 *b*, 1935 *a*, *b*, 1936). The manner of proceeding is as follows *Virus fixe* is injected into the right sciatic nerve of rabbits The animal dies eventually from rabies, and the left sciatic nerve is then removed and suspended in saline This suspension is injected into the right sciatic nerve of a further rabbit and the performance repeated When this has been carried out on several occasions the strain reacquires some properties characteristic of street virus. The term applied to a strain passed in this way is *ramené en arrière*. The properties of such a strain are as follows·

1. Negri bodies are produced on intracerebral injection of rabbits, and on intracerebral or sciatic injection of dogs
2. The incubation period after intracerebral injection in rabbits is like that of street virus.
3. *Septinévrite* is produced on rabbit injection (see p. 826).
4. Subcutaneous injection of rabbits is noninfective.
5. If a strain *ramené en arrière* is passed by intracerebral injection again it soon reverts to *virus fixe*

The differentiation between street and fixed viruses.

This is a convenient place to discuss the various points in which fixed and street strains have been found to differ

1. On intracerebral inoculation with street virus the incubation period varies from strain to strain and experiment to experiment, but the usual limits are 15 to 21 days. With the conversion to fixed virus that occurs on passage, the incubation period becomes shorter and eventually stabilized at between 3 and 6 days, according to the species of animal

Remlinger and Bailly (1937 *a*, *b*) investigated 11 strains of Tangier street virus, and found that the minimum infective titer varied from 1/2,000 to 1/100,000.

Examining a number of street strains, Mason (1942) found the usual mouse cerebral lethal dose was 10^{3}. Proca and Bobes (1940) regard the limits of infectivity of street strains as extending from 1/500–1/500,000.

Titration of rabies virus in mice. Webster (1939 *b*) showed that rabies virus can be titrated conveniently by intracerebral inoculation of mice. Brain tissue is diluted serially in 10 per cent. horse serum in distilled water, and injected in 0·03 c.c. amounts into 3-week-old W-Swiss mice, using 4 animals per dilution. With increasing dilutions of virus a critical point is reached beyond which less than 50 per cent. of mice succumb. [illegible] as containing 1 MLD. Diluti[illegible] mice. This degree of sensiti[illegible] per gram body weight injected in a similar fashion.

Habel (1940 *a*) has pointed out that up to 0·02 c.c. of an intracerebral inoculum may escape unless special precautions are taken. He recommends that the animal be deeply anesthetized, and the injection made slowly through a short, sharply bevelled 27 gage needle. On withdrawal of the needle, firm pressure should be exerted over the area.

Titration can also be performed if 0.01 c.c. of virus suspension is injected into the lower 1/3 of the gastrocnemius, dilutions of 1/320–1/2560 generally proving fatal (Webster).

In all titration experiments, a more accurate indication of the 50 per cent. end-point is secured by inoculating 6 mice per dilution and working out the calculation by the method of Reed and Muench (1938).

ANIMAL EXPERIMENTS WITH RABIES VIRUS

Routes of Infection

1. *Intracranial* Animals can be most readily infected with rabies by subdural or direct intracerebral injection The technique of subdural injection has been fully described elsewhere (see p. 859), and the intracerebral method only differs in that the needle is actually passed through the soft membranes into the cerebral tissue. Speransky (1927) has adduced experimental evidence that, after subdural inoculation, the cerebrospinal fluid disseminates the virus to all parts of the central nervous system.

The distribution of virus in the central nervous system after intracerebral injection has also been studied After inoculation of dogs with street virus, Remlinger and Bailly (1928 *d*) found virus at the site of injection after 9 days, during the previous 8 days, however, no virus could be found. Working with rabbits injected with street virus, and killing one every day, Remlinger and Bailly (1929 *d*) found that virus was still present locally after 24 hours, but not from the 2nd to 5th days. On the 6th and 7th days virus was found again The virus, therefore, rapidly disappears from the site of inoculation in dogs and rabbits, both highly susceptible to rabies In tortoises, however, which develop no symptoms, the virus may be demonstrable for months (Remlinger and Bailly, 1929 *b*).

Further confirmation of the apparent absence of virus from the cerebral tissue in the early stages of the incubation period was afforded by some observations of Cornwall and Beer (1925–6 *b*) They found that after intracranial injection of rabbits, passage of the virus could not be continued in series if the brain was removed on the 3rd day Whereas, if it was removed on the 4th day or later, passage was readily continued Lépine and Athanasiu (1947) using street virus in rabbits, detected lesions on the 4th day, but virus was not demonstrable until the 8th day.

2 *Intraneural* The fact that rabies could be transmitted by direct intraneural

Brussels strain was considerably more virulent, although it had been initiated from the same source as the Paris strain.

4. *Hanoi strain.* The strain of *virus fixe* used at the institute in Hanoi has rather active properties (Genevray and Dodero, 1936).

Antigenic Structure of Rabies Virus Strains

A number of experiments has been performed, and will be alluded to throughout these pages, in which cross immunity tests have demonstrated the antigenic similarity of various rabies virus strains Strains of *virus renforcé*, street virus, and fixed virus all appear antigenically related. Animals immunized with one strain prove resistant to other strains The rabicidal serum produced by the injection of one virus neutralizes other strains. All that has appeared from these experiments is that the Pasteur Institute (Paris) strain is a more potent immunizing agent than other strains of virus, although individual substrains vary considerably in this respect.

In recent years, however, the antigenic structure of the rabies virus has been investigated by what may prove to be a more delicate technique. Thus, Havens and Mayfield (1932 *a*) described a specific flocculation as occurring between rabies immune serum and both street or fixed virus suspensions. Further (1932 *b*), they found that rabies virus could absorb its specific antibody from antiserum, and they called this reaction "agglutinin-absorption" They investigated the antigenic structure of a number of strains and decided that at least one and probably more antigens were shared by all They suggested that antigenic differences between strains were due to a quantitative variation in fractions common to all strains (1933). It may thus be that subsequent work will show considerable antigenic variation to exist between strains of rabies virus

Infectivity of Rabies Virus Strains

The best recognized method of estimating the infectivity of any strain of rabies virus is the dilution method, serial dilutions of virus being made and tested for infectivity by injection of rabbits, preferably subdurally. In any comparative series of estimations of virus infectivity it is essential to use the same animal and the same route of injection throughout Guinea-pigs, for instance, may prove more susceptible than rabbits, and thus give a reading of greater infectivity Further, although an equivalent number of infective doses may be administered, it is found that far less guinea-pig infected brain is needed to transmit the infection (by the intravenous route) than rabbit brain (Hurst, 1937)

Working on these lines with *virus fixe*, Stuart and Krikorian (1929–30) defined a minimum lethal dose as that dose invariably producing symptoms in a rabbit of 1,400 gm weight 120 hours after subdural inoculation In preparing suspensions for titration careful attention to the diluent is essential, and 10 per cent horse serum in distilled water is probably the most useful The material should be mechanically emulsified

Fixed virus This question is fully discussed in the section on Hoegyes's method of antirabies treatment (see p 861). Here it may be said that at the introduction of this method dilutions up to about 1/5,000 usually proved infective. With the continued passage of certain strains of *virus fixe*, however, the titer has risen very considerably Thus, Remlinger (1935 *a*) found that the Tangier strain was active to a dilution of 1/900,000 Proca and Bobes (1940) found that the Bucharest strain of fixed virus, passed for over 50 years, was infective in brain tissue at 1/10,000 and sometimes up to 1/50,000, cord was infective at 1/10,000

Using Swiss mice, Mason (1942) found that various fixed strains had an average mouse cerebral lethal dose of 10^{-5}

Street virus Tested by the Hoegyes dilution method in experimental animals, it is found that street virus strains vary considerably in their infectivity Thus,

for some weeks. He found that rabbits born even before the appearance of symp-

did not contract rabies, embryos injected with street virus developed symptoms and Negri bodies could be found (de Oliveira and de Bettencourt, 1943).

8. *Rabies virus and experimental tumors* Street virus can proliferate in a Brown-Pearce neoplasm in the eye Further, the rabic infection can be passaged by inoculating pieces of tumor infected *in vivo* into the eye of another rabbit (Schoen, 1937). If tumor is growing in one eye, and street virus is injected intracerebrally or into the other eye, Negri bodies may develop in the tumor cells (Levaditi, Schoen, and Reinié, 1937 *a*). The injection of rabies virus into the lesions of rabbits bearing Shope's papillomatous tumors transmits the infection, and the animals die of rabies, but without any virus being found in the tumor (Levaditi, Schoen, and Rienié 1937 *b*) If rabbits are injected into the anterior chamber of the eye, virus only rarely localizes in the tumor.

9. *Other routes of injection.* Infection can be quite readily transmitted by injection into the tongue of various animals (see Remlinger, 1925 *a*, Reichel and Schneider, 1934, 1936). Injection into the tail is also a possible method of transmitting the infection Mice and rabbits may be infected by this route (Proca, Bobes, and Jonnesco, 1934 *b*). Remlinger and Bailly (1938 *d*) found that rabbits could rarely be infected by exposure to an atmosphere containing desiccated or pulverized virus.

The following routes may also be used intraspinal, intra-ocular, intranasal, dermal, injection into certain mucosae, injection into certain solid organs, and intraperitoneal

General Manifestations of Experimental Rabic Infection

Although many animals are susceptible to rabies, and the manifestations differ somewhat from animal to animal, and strain to strain of virus, there are certain common features

Furious rabies Furious rabies is seen in its classical form in dogs infected naturally or experimentally with street virus Furious symptoms may occur in other animals suffering from street virus infection (e g, guinea-pig and fowl). Furious symptoms, usually of relatively short duration, may be found in certain cases of *virus fixe* infection before the onset of paralysis

Animals suffering from furious rabies are at first restless ...

festations The animals usually rush about their cages in a staggering way, falling down from time to time They show a special tendency to snap and bite, harsh cries or roars are usually ...

of illness is that of para...

animals are found lying ...

out this terminal phase ... after a few days illness, although with certain attenuated strains symptoms may persist for 10 days or so (Remlinger and Bailly, 1942 *b*)

Dumb rabies Dumb or paralytic rabies is found in its most typical form in rabbits infected with rabies, especially *virus fixe*. It is found in rabic infection of many other animals also ...

form Chinese hamster, ...

injected intravenously wi...

injection was shown by di Vestea and Zagari in 1887. They injected dogs and rabbits in the sciatic and median nerves, and secured infection by this means These observations have been widely confirmed, and the possibility of transmitting rabies by direct intraneural injection is now universally accepted (Roux, 1888 *a*, Ferré, 1888, di Vestea and Zagari, 1889, de Blasi and Travalli, 1889, Moon, 1913, Nicolau and Kopciowska, 1934 *c*).

Infection has been transmitted to rabbits, dogs, and guinea-pigs by injection of the sciatic, median, vagus, facial, hypoglossal, sympathetic, and optic nerves Proof that virus actually spreads via the nerve trunks after intraneural injection is afforded by various facts. In the first place, paralysis may first involve the inoculated limb Second, the cord may show the presence of virus at the site of connection of the inoculated nerve. Third, virus cannot be isolated from the blood with any regularity, suggesting that this is not the means of dissemination of the virus. Fourth, virus has been injected intraneurally after transection of the spinal cord Later, virus was recovered from the distal, but not the proximal, part of the cord

The incubation period after neural inoculation varies according to the strain of virus and the nerve injected Thus with street virus the incubation period was about 18 days, and with fixed, 9 days (di Vestea and Zagari, 1887) In a series of experiments by de Blasi and Travalli (1889) the periods varied as follows median or sciatic nerves, 11 to 13 days, facial nerve 6 to 10 days, hypoglossal nerve 8 to 9 days, vagus nerve 7 to 9 days, sympathetic nerves 15 to 18 days

3. *Intravenous.* Rabies virus injected by this route usually produces paralytic rabies (Pasteur *et al.*, 1882). It has been found that infection is most likely to develop if the inoculum is guinea-pig brain, rabbit brain is not so infective (Hurst, 1937).

4. *Combined injection* It is said that if rabbits are injected subdurally with street virus, and during the period of incubation an intravenous injection is given, the infection is negatived and no rabies develops (Puntoni, 1921 *a*).

5. *Intramuscular* Rabbits and other animals can be quite readily infected by injections into the muscles After such an injection virus probably ascends to the central nervous system by nerve fibers The work of Goodpasture (1925) has made it appear very likely that this actually occurs Thus, he carried out a study in which he injected rabbits in the masseter muscle Infection spread to the central nervous system, probably by way of the trigeminal nerve. After such injection paralysis did not occur in the hind limbs, in the front limbs it developed more commonly on the side of the inoculation than on the other side. Histologically, there was usually an extensive cellular reaction affecting the central portion of the sensory division of the 5th cranial nerve and the gasserian ganglion

Hurst (1937) *reported that guinea-pig brain infected with passage virus is* more infective by the intramuscular route than is rabbit brain

6 *Subcutaneous* The subcutaneous route is not one of the most certain for the transmission of rabies. Thus, the dog is relatively insusceptible, especially to *virus fixe*, the rabbit is more susceptible.

Mice can be infected subcutaneously, and Webster (1937), using his specially bred susceptible stock, has found virus in the central nervous system at the site of connection of the nerve supply of the injected area The virus cannot be found until 5 to 6 days have elapsed

7. *Hereditary infection* A number of authors has pointed out that hereditary infection may occur in animals, the virus passing from a mother developing rabies shortly before delivery to her newborn offspring (Perroncito and Carita, 1887, Loir, 1903, Lanfranchi and Lenzi, 1918) Others have failed to confirm this transplacental passage of virus (e g, Zagari, 1888)

Konradi (1905, 1908, 1914, 1916) has made a special study of transplacental passage of virus He found that, in traversing the placenta, the virus loses much of its infectivity, so that animals inoculated with the fetal material should be examined

Routes of infection.

Dogs can be infected by numerous routes and develop furious or paralytic rabies with the other features of illness already described The state of nutrition of the animal does not affect its susceptibility (Remlinger and Bailly, 1932 *a*, *b*), puppies are usually much more susceptible than adult dogs (Remlinger, 1908 *e*). Beagle dogs have been much used in Webster's work.

Intracranial. In antirabies vaccine practice the usual route of injection is the subdural (see p 859). Animals infected by the subdural route are often spoken of as infected by trepanation, or as having been trepanned. The intracerebral route is widely used in experimental work. After intracranial injection with street virus, furious rabies develops in about 15 to 21 days. Fixed virus usually produces paralytic rabies, but sometimes the furious form, the incubation period being usually under 8 days.

Intraneural As we have already mentioned, dogs may be infected by injection into the median, sciatic, or other nerves (see p. 817). The first symptoms usually develop in 10 to 21 days' time, depending on the site of inoculation and the strain of virus

Intra-ocular. Injection into the anterior chamber of the eye usually secures infection (Roux and Nocard, 1890, Remlinger, 1904 *g*). The virus probably spreads to the brain by the optic and other nerves.

Dermal Intradermal injection usually fails to transmit the infection, and it has been reported that superficial scratches rubbed with virus do not become infected (Babès and Vasilu, 1911)

Intramuscular. Injection into muscles such as those of the neck is usually positive, but Marie (1912 *b*) reported that intramuscular injection of the abdominal walls was only positive in 40 per cent. of cases A special application consists in injecting animals in the tongue. As compared with intracerebral injection, 10 times as much virus is needed to infect if the inoculation is made in the tongue, 40 times if in the neck, and 1,000 times if in the muscles of the hind leg (Webster, 1942).

Intravenous. Dogs injected intravenously usually develop paralytic rabies (Pasteur *et al*, 1882, Remlinger and Mustapha Effendi, 1904, Remlinger, 1904 *g*). However, small doses of virus may result in the development of furious manifestations (Pasteur *et al*, 1884)

Intravesical. Dogs have been infected by instillation of the bladder (Remlinger and Bailly, 1938 *f*).

2. Rabbit

Canine rabies was early found to be transmissible to rabbits (see, e.g., Galtier, 1879, 1881, 1890, Pasteur *et al*, 1881 *a*, Raynaud and Lannelongue, 1881, Helman, 1889, Leclainche and Morel, 1899). The susceptibility of the rabbit to rabic infection is of the greatest advantage in experimental work and in antirabies practice. Of particular merit is the factor of safety to the experimenter, as the rabbit practically always develops paralytic rabies, and shows no tendency to bite.

In Tonkin, Dodero (1939) reported a shorter incubation period in infected rabbits in the summer

Routes of infection.

Rabbits can be infected by all the common routes, subdural, intracerebral, intraneural, intra-ocular, dermal, subcutaneous, and intramuscular. They may also be infected by rubbing virus onto a patch of recently shaved skin (Remlinger, 1905 *f*)

that street virus produces furious rabies and *virus fixe* dumb rabies, but there are so many exceptions to this rule that it scarcely applies to animals other than the dog

Animals suffering from paralytic rabies may show a short preliminary phase of excitation, and there may be a tendency to bite throughout the illness. Very soon, if not as the first manifestation, paralysis develops, affecting characteristically the lower extremities. At first the animal is ataxic, but soon it falls to the ground and is unable to rise. The lower jaw is usually paralyzed also. The animals usually waste before death, and polyuria may occur. Albuminuria is very frequent (Auffret and Dodero, 1940 *b*).

Wasting. There has been some discussion regarding the occurrence of wasting as a manifestation of rabic infection. Thus, Lamb and McKendrick (1909) found that certain rabbits injected subdurally with street virus (or subcutaneously with fixed virus) kept in good health for some time, but later became wasted and died with no other manifestation of infection, in certain cases the wasting set in earlier and was more progressive. The virus could only be demonstrated by passage of infected tissue. Remlinger (1927 *d*), however, considered that the existence of such a condition as "consumptive" rabies in animals had not been proved.

Temperature. A number of workers has recorded a rise of temperature in rabies (e.g, di Vestea and Zagari, 1887; Hoegyes, 1888, Babès, 1888, Roux and Nocard, 1890). This rise usually occurs about 6 to 7 days after the inoculation of virus, although it may occur earlier. It is more uniformly present in *virus fixe* infections than with street virus. The rise of temperature is of importance, as it usually occurs concomitantly with the presence of virus in the saliva, and therefore with the potential infectivity of the animal (Nicolas, 1906).

Respiration. Ferré (1888) drew particular attention to an increase in the respiratory rate. This increase begins in the incubation period and persists throughout the illness, except that in the terminal paralytic phase of street virus infection the respiratory rate usually becomes lessened

Blood changes Certain authors have studied the blood counts in experimental rabies and found a polynucleosis (Courmount and Lesieur, 1901, Nicolas, 1903). Nicolas and Bancel (1905) suggested, however, that this rise was nonspecific as it occurred after injection of normal as well as rabic cords.

Biochemical changes The blood urea has been found to rise in rabid dogs and rabbits, and glycemia may occur (Remlinger and Bailly, 1937 *c, d*) There is an increase in the blood chlorides, especially in the cells (Remlinger and Bailly, 1937 *e*).

The serum of rabid rabbits has been found to exert a neutralizing effect on atropine (Tzekhnovitzer and Goldenberg, 1929)

The adrenalin content of the adrenals has been found much diminished in the terminal stages of *virus fixe* infection (Porak, 1912)

Recovery. Animals seldom recover from experimental rabies but there were certain references to this in the older literature (see, e g, Pasteur *et al*, 1882, 1884, Remlinger and Mustapha, 1904, Vincent, 1907, Remlinger, 1907 *c*, 1919 *d*) Johnson (1943) has observed several hundred dogs with experimental rabic infection and has not seen a recovery from furious rabies In some instances, dogs may develop an abortive type of illness from which they recover.

ANIMALS SUSCEPTIBLE TO RABIES VIRUS

1. Dog

Virtually all our modern knowledge of the virus, and of the prevention of rabies, dates from the early experiments of Pasteur and others on the transmission of the infection to the dog (see, e g, Pasteur *et al*, 1881 *b*, 1882, 1884, Pasteur, 1887, Ernst, 1887, Finkelstein, 1887, Gamaleia, 1887 *b*, Helman, 1889, Ferré, 1888, 1889, Marie, 1907 *b*).

(*f*) *Fulminating form* This type of infection is characterized by a rapid and practically asymptomatic death [illegible]

Factors influencing symptomatology.

Virus fixe always gives paralytic rabies, but street virus usually produces one of the other forms The site of inoculation with street virus influences the subsequent manifestations (Remlinger); thus subdural and intracerebral injection usually produce furious rabies Intra-ocular injection gives rise to spasmodic rabies, and nasal inoculation to attenuated furious, dyspneic, or pseudosepticemic rabies. Intramuscular inoculation may give localized tetanic convulsive movements, intravenous injection may produce a flaccid paraplegia

4. Mouse

Mice have been used extensively of recent years, especially in diagnostic work and titration experiments. They are probably about 10 times as susceptible as guinea-pigs or rabbits They can become infected following the bite of a rabid dog or cat, or by ingesting an infected cadaver (Remlinger, 1908 *d*). Mice can be infected experimentally with street or fixed virus by the following routes intracerebral, intramuscular, subcutaneous, intraperitoneal, intranasal, and by injection into tongue or tail, approximately 100 times as much virus is needed to infect by [illegible] subcutaneous route, as compared with the [illegible], Jonnesco, 1934 *b*, Proca, Bobes, and Jon- [illegible] and Leach, 1940 *a*, Remlinger and Bailly, 1940 *b*, 1941 *a*, *b*, Sabin *et al*, 1940, Mason, 1942, Baranovskaya, 1943, Kligler and Bernkopf, 1943). Of recent years Webster has recommended a specially bred susceptible strain of mouse (Webster and Dawson, 1934–5, Webster, 1936, 1937, 1939 *b*, 1942). Any ordinary "laboratory" mouse may, however, be almost equally well used

Age plays an important part in determining susceptibility to rabic infection Casals (1940 *a*) found that 7–9 day old mice were more susceptible than older mice however injected, 20-day-old mice were more susceptible than 60-day to peripheral but not intracerebral injection of fixed virus, 20- and 60-day mice were equally susceptible to street virus (see also Casals and Webster, 1940)

Mice suffering from symptoms due to fixed virus are abnormally susceptible to the effect of glucose injected intraperitoneally, probably because of the resulting dehydration (Hoyt *et al*., 1939).

Clinical features.

The following types of illness may develop in infected mice (Remlinger and Bailly, 1940 *b*, 1942 *c*),

Furious rabies This type is seen chiefly after intracerebral or peripheral injection of street virus. The animal makes rapid movements and jumps about the cage, tending to bite other animals Paralysis may develop These features last from 1–3 days, and death is often sudden After intramuscular injection there may be a tendency to automutilation by biting Another symptom is a marked tendency to scratch

Paralytic rabies After an incubation period of 7–19 days following injection of fixed virus, the animal develops tremors, an unsteady gait, incontinence and definite paralysis, either hemiplegic or ascending The onset is often sudden and these features may not be observed

Other forms Remittent, pseudotetanic spasmodic, atypical fulminating, and spasmodic initial monoplegic types have been described

Rabbits inoculated intracranially with *virus fixe* usually develop paralytic symptoms after 5 days, and are dead by the 8th day, although the disease may sometimes progress even more quickly (Grysez, 1941).

In addition to the routes of infection commonly used in rabies experimental work, certain others have been employed.

Corneal. Rabbits can be infected by corneal inoculation of either street or fixed virus (Kraus and Fukuhara, 1909, Levaditi and Schoen, 1935 *a*).

Ingestion Ingestion of rabies virus was said to prove infective (Galtier, 1881), but the majority of present-day investigators does not believe that infection can be transmitted by this route, at any rate with any readiness.

Injections into the viscera. Levaditi and Schoen (1935 *a*) reported that infection resulted after injection of the parotid gland, adrenal, testis, or ovary.

Nasal. Rabbits can be infected by swabbing the nasal mucosa with virus (Galtier, 1890, Remlinger, 1904 *b*, Levaditi and Schoen, 1935 *a*).

Other mucosae. In the course of their study on the local production of Negri bodies in mucous membranes, Levaditi and Schoen (1935 *a*) found that manifestations of rabic infection followed inoculation of the conjunctival, lingual, tracheal, and intestinal mucosae.

3. Guinea-pig

Guinea-pigs have been fairly extensively used in experimental work (see, e g, Pasteur *et al.*, 1884, Gibier, 1884, Lamb and McKendrick, 1909, Nicolle, 1917, Panisset and Dischamps, 1920, Figueira, 1924, Schweinburg, 1932 *b*, Jacotot, 1937, Virga, 1938, Raynal and Lieou, 1940 *a*).

Remlinger, in particular, has studied experimental rabies of the guinea-pig, and his work is still the most complete study (1917 *a*, *b*, *c*).

Routes of inoculation.

The following routes are in general use. intracerebral or subdural, intra-ocular, nasal, intramuscular, and intravenous The animals may be infected by intracardiac injection *Virus fixe* injected intraperitoneally is usually noninfective, but a preliminary dose of India ink may produce a positive result (Marie, 1932, 1934). Remlinger (1906 *a*) was able to secure infection by injecting lymph glands enlarged by tuberculosis. The mucosae are susceptible to invasion by street virus (Piringer, 1945).

Clinical features.

Remlinger has described the following manifestations of rabies in the guinea-pig

(*a*) *Furious rabies.* The animal's hair bristles, it is excited in its movements, and often rushes about the cage, falling down from time to time, sexual excitement also may be very marked The respirations are accelerated The animals often bite their companions, but not man.

(*b*) *Attenuated furious rabies* The symptoms in this type of infection are as in furious rabies, only very much milder

(*c*) *Dyspneic form* This type of reaction is characterized by little else than a very accelerated respiration rate

(*d*) *Pseudosepticemic form* In this type of illness the animal is laid low by the virulence of the infection without showing evidence of excitation. In certain cases the animal may die suddenly, after some weakness and perhaps slight paralysis, about 3 to 5 weeks after inoculation (Remlinger and Bailly, 1931 *b*)

(*e*) *Spasmodic form.* This type usually follows intra-ocular injection and begins by an intense local pruritus and inflammatory reaction in the eye The animal has pharyngeal spasms and expels saliva With the progress of the infection, convulsions, spasms, and guttural cries occur

occur in the cerebellum where there is perivascular and interstitial inflammation (see also Veeraraghavan and Philipsz, 1940).

Stork. Subdural inoculation of *Ciconia ciconia* was found to give rise to paralytic rabies (Remlinger and Bailly, 1936 *b*).

Pheasant This bird was infected by Jacotot (1938)

Peacock. Jacotot and Le Roux (1938) transmitted infection to a peacock.

Other birds. Canaries, geese, and ducks can also be infected, although it may not be possible to pass the virus in series indefinitely (Marie, 1904 *a*). The sparrow is also susceptible (Veeraraghavan and Philipsz, 1940).

14 *Tortoise.* Many years ago it was shown that the tortoise was refractory to rabies (Remlinger, 1904 *b*, 1905 *b*). More recently, interest has been revived, be- [illegible] remain latent and be [illegible] time (Remlinger and [illegible] 1). Thus, street virus [illegible] *Testudo mauritanica* (Remlinger and Bailly, 1931 g, 1932 *a*). The animals did not, however, show any sign of infection A similar state of affairs obtains in the case of certain other tortoises e g, *Clemmys leprosa*, where virus was recovered, in one experiment, after 150 days (Remlinger and Bailly, 1932 *a*), and *Cynixys belliana tortues* (Mezger, 1932).

15. *Toad and frog.* Unlike the tortoise, virus only survives for a few days after intracerebral injection (Remlinger and Bailly, 1929 *e*, 1930 *g*, *h*, 1932 *a*) The animals prove quite refractory and no symptoms develop After injection into the dorsal lymph sac, virus undergoes a gradual attenuation of virulence (Babès and Cerchez, 1891).

DISTRIBUTION OF VIRUS IN INFECTED ANIMALS

Site of Inoculation

In normal mice and guinea-pigs, street virus introduced peripherally remains viable in the muscle for at least 4 days, and invades the nervous system within 24–48 hours (Habel, 1941 *b*).

Central Nervous System

Brain and cord After intracranial injection, virus is to be found locally for a comparatively few hours only. During the next 3 to 4 or more days no virus can be found at the site of inoculation, but reappears thereafter. During the first few days after injection the virus is spreading to the bulb, cord, and peripheral nerves, but without causing any symptoms, although there may be a rise of temperature (see also p 810) A number of authors has recorded the presence of virus in the bulb of animals injected by various routes during this incubation period (di Vestea and Zagari, 1887, Gamaleia, 1887 *c*, Roux, 1888 *a*, Remlinger, 1905 *c*, *d*, Levaditi, Nicolau, and Schoen, 1924 *c*, 1926, Palawandow and Serebrennaja, 1931 *b*).

After intracerebral injection, street virus has been found in large quantity in the facial nucleus 5 days before the onset of symptoms (Remlinger and Bailly, 1928 *d*) With the onset of symptoms it is found that virus has spread to all parts of the central nervous system, although in the dog certain parts may be found avirulent, the distribution being rather irregular (Koch, 1929, Remlinger and Bailly, 1931 *a*).

After neural injection virus can first be isolated from the spinal cord in the area associated with the inoculated fibers (di Vestea and Zagari, 1889). At a later stage in the disease, the virus can be isolated from all parts of the cord. After injection by other routes also, virus can be isolated from the cord, as from other parts of the central nervous system For example, after intramuscular injection (gastrocnemius) in mice, virus appears in the lumbar cord 3–5 days later and passes

Histological lesions occur in the brain and cord, and in the posterior root ganglia after peripheral inoculation.

Other Animals

5. *Monkey.* Monkeys can be infected subcutaneously with *virus fixe* (Helman, 1889; Lamb and McKendrick, 1909), also subdurally, intramuscularly, and intraperitoneally. Fixation of street virus can be secured by repeated subdural passage in monkeys (Acton and Harvey, 1912–13). Monkeys can be readily infected with street virus by injection of the neck muscles.

6. *Cat.* Cats can be infected by subdural or intra-ocular injections, but have not been used extensively in experimental work; the symptoms may be furious or paralytic.

7. *Fox.* França (1905 *b*) transmitted street virus to the fox by intramuscular injection; the disease assumed either the furious or paralytic form.

8. *Rodents.* Gibier (1884) found that rats were susceptible, and Remlinger (1904 *c*) infected rats and mice. França (1905 *a*) found that the following members were susceptible. *Mus decumanus, Mus rattus, Mus musculus,* and *Arvicola incertus.* Fermi (1907) found that rats and mice were especially susceptible to Sassari fixed virus.

Rat. Rats are susceptible to infection with rabies virus by the ordinary routes of infection, except that they are said to be comparatively insusceptible to subcutaneous injection of street virus, although younger animals are more susceptible than older (Legezynski and Markowski, 1928 *b*).

The Chinese hamster can be infected, both with street and fixed viruses, by intracerebral injection (Yen, 1936 *a, b*). The resulting disease is usually paralytic and Negri bodies are found.

[illegible]) which was [illegible] bite, and it [illegible] and Negri bodies were present (Vianna, 1929).

9. *Horse.* The horse can be infected experimentally with rabies, and this has been reaffirmed by Jacotot and Le Roux (1937). Infection can be transmitted by the intracerebral route and paralytic rabies develops, there may, however, be some signs of excitation and attempts to rise.

10 *Calf* Calves may be infected by intracerebral injection and develop paralytic rabies (Lewthwaite, 1930, Jacotot and Le Roux, 1937)

11. *Sheep* This animal can be infected with rabies quite readily.

12. *Hedgehog.* Hedgehogs are susceptible to both street and fixed viruses (Jonnesco, 1927 *a*, 1932 *a*) After subdural inoculation paralysis develops in 7 to 8 days, the animal may have convulsions and tetanic spasms, and attempt to bite *Passage of virus fixe* through hedgehogs increases its virulence for rabbits, as well as dogs, which may develop furious symptoms

13. *Birds. Hens and cocks* can be quite readily infected with rabies and develop paralytic manifestations (Gibier, 1884, Pasteur, Chamberland, and Roux, 1884, Remlinger and Bailly, 1929 *a, f*, 1930 *d*, Veeraraghavan and Philipsz, 1940). Sometimes, after intracerebral injection, there may be a stage of furious rabies, terminating in paralysis, recovery may sometimes occur Microscopically, the main changes are to be found in the cerebellum, there is an inflammatory reaction near the Purkinje cells, with perivascular cuffing In the cord, hemorrhages and leukocytic infiltrations are found dorsally Negri bodies may occur in the cerebrum

Pigeon Rabies of the pigeon has been studied in particular by Remlinger and Bailly (1929 *c, f, g*, 1930 *e*), who used street virus Infection is best carried out by the intracerebral route and results in the development of paralytic rabies after about 10 to 24 days, there are disorders of equilibration and flight, histologically, changes

occur in the cerebellum where there is perivascular and interstitial inflammation [illegible]

Peacock. Jacotot and Le Roux (1938) transmitted infection to a peacock.

Other birds. Canaries, geese, and ducks can also be infected, although it may not be possible to pass the virus in series indefinitely (Marie, 1904 *a*). The sparrow is also susceptible (Veeraraghavan and Philipsz, 1940).

14. *Tortoise.* Many years ago it was shown that the tortoise was refractory to rabies (Remlinger, 1904 *b*, 1905 *b*). More recently, interest has been revived, because it appears that after intracerebral inoculation virus may remain latent and be recovered from the brain in a living condition after a long time (Remlinger and Bailly, 1929 *e*, 1932 *e*, Remlinger, Manouélian, and Bailly, 1931). Thus, street virus was recovered 302 and 285 days after intracerebral injection of *Testudo mauritanica* (Remlinger and Bailly, 1931 *g*, 1932 *a*) The animals did not, however, show any sign of infection. A similar state of affairs obtains in the case of certain other tortoises: e g, *Clemmys leprosa*, where virus was recovered, in one experiment, after 150 days (Remlinger and Bailly, 1932 *a*); and *Cynixys belliana tortues* (Mezger, 1932).

15. *Toad and frog* Unlike the tortoise, virus only survives for a few days after intracerebral injection (Remlinger and Bailly, 1929 *e*, 1930 *g*, *h*, 1932 *a*). The animals prove quite refractory and no symptoms develop After injection into the dorsal lymph sac, virus undergoes a gradual attenuation of virulence (Babès and Cerchez, 1891).

DISTRIBUTION OF VIRUS IN INFECTED ANIMALS

Site of Inoculation

In normal mice and guinea-pigs, street virus introduced peripherally remains viable in the muscle for at least 4 days, and invades the nervous system within 24–48 hours (Habel, 1941 *b*)

Central Nervous System

Brain and cord After intracranial injection, virus is to be found locally for a comparatively few hours only During the next 3 to 4 or more days no virus can be found at the site of inoculation, but reappears thereafter. During the first few days after injection the virus is spreading to the bulb, cord, and peripheral nerves, but without causing any symptoms, although there may be a rise of temperature (see also p. 820) A number of authors has recorded the presence of virus in the bulb of animals injected by various routes during this incubation period (di Vestea and Zagari, 1887, Gamaleia, 1887 *c*, Roux, 1888 *a*, Remlinger, 1905 *c*, *d*, Levaditi, Nicolau, and Schoen, 1924 *c*, 1926, Palawandow and Serebrennaja, 1931 *b*).

After intracerebral injection, street virus has been found in large quantity in the facial nucleus 5 days before the onset of symptoms (Remlinger and Bailly, 1928 *d*). With the onset of symptoms it is found that virus has spread to all parts of the central nervous system, although in the dog certain parts may be found avirulent, the distribution being rather irregular (Koch, 1929, Remlinger and Bailly, 1931 *a*)

After neural injection virus can first be isolated from the spinal cord in the area associated with the inoculated fibers (di Vestea and Zagari, 1889). At a later stage in the disease, the virus can be isolated from all parts of the cord. After injection by other routes also, virus can be isolated from the cord, as from other parts of the central nervous system. For example, after intramuscular injection (gastrocnemius) in mice, virus appears in the lumbar cord 3–5 days later and passes

quickly to the brain (Webster, 1939 *b*). Working with mice injected intraperitoneally, Kligler and Bernkopf (1043) found virus in the upper cord after 72 hours, after subcutaneous inoculation in the hind leg virus was first found in the lumbar and thoracic cord, while after inoculation in the fore leg it appeared first in the cervical cord. At a later stage, virus was found in all parts of the CNS.

Cerebrospinal fluid. There is some question as to whether the cerebrospinal fluid may contain the virus or not. It seems that unless cerebrospinal fluid is obtained by puncture, and not during the removal of the brain at autopsy, nerve tissue may contaminate the fluid and give a false positive result (Kerbler, 1933).

Following subdural inoculation, there would seem to be no doubt that virus is disseminated to the central nervous system by the cerebrospinal fluid (see p 828), but it is uncertain as to how long the fluid remains infective.

Septinévrite. This term has been used by French-speaking authors to signify the general dissemination of rabies virus throughout the whole nervous system after injection into any one part of it, whether central or peripheral (Nicolau, 1928, Nicolau and Serbanescu, 1928, Nicolau and Galloway, 1928; Nicolau, Dimancesco-Nicolau, and Galloway, 1929, Nicolau and Kopciowska, 1934 *c*). *Virus fixe* does not produce such general dissemination of *septinévrite* as constantly as does street virus.

After intracerebral injection, a street strain can be isolated from the brachial nerves on the 5th day, and the sciatics by the 6th day, it can also be isolated from the small subcutaneous nerve fibers

The spread of virus throughout the nervous system can be demonstrated, not only by finding the virus in the nerves, but also by the occurrence of specific histological changes The reaction is an interstitial neuritis with infiltration of mononuclears and plasma cells, perivascular cuffing occurs.

Further proof of this general spread of virus throughout the central nervous system has been afforded by the study of injections into animals in which certain nerve paths have been sectioned. Thus, virus was injected into the sciatic nerve after transection of the cord Virus was later isolated from the distal part of the cord and the contralateral sciatic nerve, but not the proximal cord. This clearly showed that nerve paths were the direct means of spreading the virus Further, the cerebrospinal fluid did not appear to play any part (di Vestea and Zagari, 1889)

Another line of approach to this problem was to cut the sciatic nerve shortly after its emergence from the spinal column, and then inject virus intracerebrally. Virus was not isolated from the nerve peripheral to the section, but it occurred in the contralateral nerve (Nicolau and Serbanescu, 1928, Nicolau and Mateiesco, 1928, Nicolau, Dimancesco-Nicolau, and Galloway, 1929).

Other Organs

Blood There has been some difference of opinion over the infectivity of the blood. Thus, certain workers have failed to isolate the virus therefrom (see, e g, di Vestea and Zagari 1887, Helman, 1889). On the other hand, quite a number of workers has isolated virus in both fixed and street virus infections (see, e g, Pasteur *et al.*, 1881 *a*, 1884, Marie, 1905 *b*, Schweinburg, 1932 *a*)

Marie and Urbain (1931) injected rabbits with *virus fixe* by trepanation In the early days of the incubation period, flour, gonacrine, or tuberculin was injected into the subarachnoid space These injections had the effect of making virus appear in the blood

Remlinger and Bailly (1939 *b*) have isolated virus from ticks infesting infected rabbits

Eyes Virus can be found in the retina, choroid, vitreous and aqueous humors (Courmont and Nicolas, 1903, Remlinger and Bailly, 1940 *c*).

Saliva. A number of authors has studied the infectivity of the saliva in dogs

infected naturally or experimentally (e.g., Galtier, 1879, Pasteur *et al.*, 1882, 1884, Roux and Nocard, 1890, Nicolas, 1906, Cruickshank and Wright, 1914). Virus may be isolated from the saliva 3 to 4 days before the onset of symptoms, as well
found 7 days before the onset
may continue to be excreted
ux (1903) was able to show
virus has been isolated from
the submaxillary and other salivary glands, it is highly probable that the virus is excreted by these organs (Raynaud and Lannelongue, 1881, Pasteur *et al.*, 1884; Poor, 1906; Cruickshank and Wright, 1914). The characteristic hydrophobic froth is probably noninfective (Remlinger, 1928 *b*), saliva produced in response to injection of pilocarpine proves noninfective (Remlinger, 1904 *e*). Rabbit saliva may prove infective (Pasteur *et al.*, 1881 *a*).

Lacrimal glands. Virus has been isolated from the lacrimal glands in experimental rabies of dogs and rabbits (Tscheschkow, 1931) It has also been isolated from the lacrimal gland of Harder in rabbits infected with *virus fixe*, and dogs infected with both street and fixed viruses (Remlinger and Bailly, 1938 *c*).

Mammae. Bardach (1887 *b*) found virus in the mammary tissue and milk of lactating rabbits The milk of infected guinea-pigs may rarely contain the virus (Remlinger and Bailly, 1932 *a, d*).

Liver. The presence of virus has been recorded in the liver (Remlinger and Bailly, 1931 *a, b*; Schweinburg, 1932 *a*)

Kidneys. This organ may contain virus (Remlinger and Bailly, 1931 *a, f, b*)

Adrenals

Spleen

and Bailly,

Pancreas

Lungs. Bert (1878) examined rabid dogs and reported that the pulmonary secretion was probably infective. Infectivity has been found by Remlinger and Bailly (1934 *a*), examining rabbits, dogs, guinea-pigs, and cats

Testes. These organs contain the virus only on rare occasions (Schweinburg, 1932 *a*).

Lymphatic system. Virus was found in the mesenteric, axillary, and inguinal glands a short time after intraperitoneal injection of mice and occasionally reappeared in the mesenteric glands after some days (Kligler and Bernkopf, 1943).

Autosterilizable Neuro-infections

This term has been applied by French authors to a condition where no virus can be isolated from an organ almost certainly infected It is supposed that the reaction of the host is so efficient that the virus is destroyed and cannot be isolated. The existence of this condition has been postulated in rabies as in other neurotropic virus diseases (Levaditi, Sanchis-Bayarri, and Schoen, 1928, Remlinger, 1928 *c*, and others)

n the

fato
virus (Nicolau, Mathis, and Constantinesco, 1933) After neural inoculation in rabbits, the cord may show an intense reaction without the presence of virus,

th

from a supposed case of autosterilizable neuro-infection, guinea-pigs and mice should be injected, owing to their greater susceptibility.

PATHOGENESIS OF EXPERIMENTAL RABIES

Portal of entry Animals can be infected by a variety of routes, but most readily by those in which virus is applied more or less directly to nerve fibers. Thus, intracranial and intraneural injections regularly secure infection. Animals can also be infected by the dermal, subcutaneous, and intramuscular routes, and by injections into the tongue or tail After injections by these methods also it is presumed that virus spreads to the central nervous system by nerve fibers.

Spread of the virus. The spread of virus in the nervous system has already been fully discussed (*septinévrite*, see p. 826). Thus, after both intraneural and intracerebral injection, virus is disseminated to all parts of the central and peripheral nervous system. Its presence may be detected by animal inoculation tests, and by the occurrence of histological lesions, including Negri bodies in the endoneurocytes

Further proof of the rôle of the actual nerve fibers in the spread of rabic infection has been afforded by experiments in which the spinal cord was cut. After *injection of the sciatic nerve, virus could be found only in the distal part of the* cord and the contralateral nerve. Also, when virus was injected intracerebrally after section of the sciatic nerve, virus was not found distal to the cut, but was present in the contralateral nerve.

Yamaki (1937) injected rabbits intravenously with virus, and studied chronaxia of various muscle groups His studies led him to postulate a neural spread of virus, as signs of nervous irritation were evident during the prodromal period

These experiments showed that it was unlikely that the cerebrospinal fluid playe[illegible] injection. [illegible] agent [illegible] somewhat different after subdural injection. Here the work carried out by Speransky (1927) seems to show convincingly that virus is disseminated to other parts *of the central nervous system* by the cerebrospinal fluid, as indeed *might reasonably* be expected This author found that when cerebrospinal fluid was drawn off prior to subdural injection, the incubation period was prolonged Also, by a special technique, he was able to infect the surface of the brain without the needle passing through the cerebrospinal fluid In such a case the incubation period was again prolonged Finally, he showed that intraspinal injection of antiserum neutralized subdural inoculations of virus made a short time earlier or later.

The possible rôle of the blood has still to be considered Is virus disseminated through the body by the blood? That this is unlikely is suggested by the comparatively few occasions on which virus has actually been isolated from the blood Schweinburg and Windholz (1930) have investigated the rôle of the blood by joining two rats together by the skin One animal only was infected with rabies and eventually died therefrom. The other animal did not contract rabies This *experiment supports the opinion that the virus does not spread* by the blood, as presumably there was some vascular communication between the two animals Although to postulate spread by the blood does not prove attractive, this route would appear to operate in those cases of hereditary rabies developing in the newborn of infected mothers, some being in the incubation period and not actually rabid (see p. 818)

Primary tissue reaction With regard to the primary tissue reaction in rabies, no series of experiments quite comparable to that of Hurst in poliomyelitis (Ch LXXXIV) appears to have been carried out, although certain observations have been made.

A series of experiments was carried out by Laignel-Lavastine and Voison (1906) in which they injected rabbits intracerebrally, killing one every day They found that on the 2nd day the nerve cells of the cord showed only some nuclear chromatolysis For the next few days changes were those of swelling, distortion, and

eventual disappearance of the Nissl bodies, and vacuolation of the cytoplasm Lastly neuronophagia was found by the 6th day.

Goodpasture (1925) carried out a series of experiments in which rabbits were injected in the masseter muscle. The first evidence of injury to the nervous tissue was detected in the nerve cells of the gasserian ganglion. It was found that these cells might become completely necrotic without there being any evidence of cellular reaction in the surrounding tissue.

It appears, therefore, that the primary tissue reaction in rabies is a primary neuronal degeneration, as in poliomyelitis

PATHOLOGY OF EXPERIMENTAL RABIES

Central Nervous System

[illegible]

infections Further, there may be a tendency for the reaction with *virus fixe* to be more cellular.

The meninges of the brain and cord are usually edematous and hyperemic and may be infiltrated with mononuclear cells Minute hemorrhages are a characteristic feature of rabic infections, and occur perivascularly and diffusely throughout the brain and cord, perivascular "cuffing" is another feature, but of somewhat variable intensity. The epithelium of the central canal may show proliferation, and hemorrhages may surround the canal Microgliosis may be found in certain cases Demyelination does not occur (Grinker).

Nerve cell changes Degenerative changes are usually found in the anterior horn cells and may also be noted in the Purkinje cells Changes in the neurofibrilliary apparatus have attracted some attention (Cajal and Garcia, 1904, França, 1905 *b*, Marinesco and Draganesco, 1932, Manouélian, 1935 *c*, 1936 *a*) These changes occur in infections with both fixed and street virus and take the form of overstaining, hypertrophy, and fusion into thick cords, a plexus-like formation may eventually develop Manouélian (1935 *c*) drew attention to these changes, particularly in the spinal ganglia, but they occur also in the nerve cells of the bulb, Ammon's horn, vagus nucleus, and spinal cord These neurofibrillary alterations may be very prominent in the nerve cell in the centre of a rabic nodule, even though the cytoplasm and nucleus of the cell have disappeared (Manouélian).

Changes have also been described in the mitochondria, Golgi apparatus, and Nissl bodies. Thus, Tupa (1929) reported that the nerve cells of the rabbit's brain infected with *virus fixe* showed poorly staining mitochondria, poorly stained and hypertrophied Golgi apparatus, and fragmentation of the Nissl bodies.

Babès nodules These lesions have already been described, and the lesions in animals resemble exactly those of the human disease (Babès, 1892, Germano and Capobianco, 1895, Anglade and Chocreaux, 1902, França, 1905 *b*). Nerve cells are surrounded by a nodule of microglial and mononuclear leukocytes, in severe cases neuronophagia occurs These changes are found in the bulb and to a lesser extent elsewhere in the central nervous system, and occur in both street and fixed virus infections

Van Gehuchten and Nelis nodules These nodules have already been described under the section on human pathology, and their appearance in animals does not differ (Anglade and Chocreaux, 1902, Manouélian, 1903, França, 1905 *b*). Nerve cells in the spinal ganglia are surrounded by proliferated capsular and leukocytic cells, there is also an interstitial inflammatory reaction with mononuclear infiltra-

tion In the severer lesions neuronophagia occurs. Van Gehuchten lesions occur in both street and fixed virus infections.

Other changes. Experimental rabies induces a definite alteration in the mineral constituents of the rabbit brain. Romenski (1935) found that the sodium was diminished and the calcium increased, in the cord the calcium, magnesium, and potassium were increased.

Globules of glycogen may be found in the nerve cells in the bulb and Ammon's horn and in other parts of the central nervous system (Jonnesco and Teodasiu, 1929).

Other Parts of the Body

Salivary glands. Histological changes in these glands are to be expected, as the saliva is usually infective and forms the means of transmitting the causal agent, they have been described by certain authors (Bosc, 1903 *b*, Babès and Jonnesco, 1909 *a*, Manouélian, 1914). The acinar cells usually show degenerative changes, and there is infiltration of the parenchyma and interstitial tissue with leukocytes and macrophages, adenomatous lesions have also been noted.

Mucous membranes. Manouélian and Viala (1928 *a*) have described microscopical lesions of the mucosae of the mouth and tongue; these take the form of minute abscesses [illegible] cells

Muscles. Loss [illegible] have been recorded in rabid [illegible]

Spleen Lesions have been described in the spleen in both street and fixed virus infections (Babès and Jonnesco, 1909 *b*). Thus, the follicles are hypertrophic, hyperemic, and hemorrhagic, and there may be degeneration of certain of the central cells

Kidneys. Changes are said to occur in the kidney in rabic infections of experimental animals (Babès and Jonnesco, 1909 *c*). The glomeruli are congested and may show hemorrhages, they may also be infiltrated with fibroblasts, mononuclears, and even polymorphs There is some cellular infiltration of the interstitial tissue also.

Adrenals. Marked karyorrhexis has been reported in the adrenals of animals infected with *virus fixe* (Nicolas and Bonnamour, 1905).

Testes Babès (1909 *b*) found that spermatogenesis was active in dogs suffering from furious rabies, but diminished in paralytic rabies

CAUTERIZATION IN EXPERIMENTAL RABIES

A number of workers has explored the effect of cauterization on wounds experimentally infected with rabies virus Thus Babès and Talasescu (1894) infected wounds of dogs or rabbits with fixed virus, and cauterized with the thermocautery If the wounds were cauterized more than 25 minutes after infection, rabies developed Cabot (1899), on the other hand, who infected guinea-pigs intramuscularly with fixed virus, found that when the track of the needle was treated 24 hours later, rabies could be prevented, fuming nitric acid and the cautery being more effective than silver nitrate Nitric acid was also found effective in experimental work with guinea-pigs by Poor (1911) and Rosenau (1935), and Jordan *et al* (1939–1940) claimed that ultraviolet light was of value.

The most recent work is that of Shaughnessy and Zichis (1943) who infected guinea-pigs intramuscularly with fixed virus They found that treatment applied within 30 minutes was definitely more effective than when applied after 6 hours They showed that irrigation with soft soap was just as effective as the highly destructive cauterization with nitric acid. Tincture of iodine also proved valuable.

THERAPY OF EXPERIMENTAL RABIES

A variety of chemotherapeutic drugs has been tried in experimental rabies (fixed virus), but without effect e g, plasmoc'
pyridium (Hoyt, Fisk, and Thienes, 1935).
ineffective (Bruni and Buda, 1939, Kirk, 193
Sparteine sulfate has also been used without
Bailly, 1932 *a*, *c*, Hoyt, Fisk, and Thienes, 1935)
to 43° C for 15 to 20 minutes on several occasions during the incubation period did not prevent a fatal result (Remlinger, 1906 *d*) The administration of anesthetics does not influence the illness resulting from rabic infection (Remlinger and Bailly, 1932 *a*, Sulkin, Zarafonetis, and Goth, 1946) The therapy of experimental rabies by antirabic sera has proved quite efficacious and is fully discussed below (see p 851) Antirabies treatment may also be effective (see p 849).

OTHER PROPERTIES OF THE RABIES VIRUS

Morphology, Filtrability, and Size

Elementary bodies have not been much studied, although they have been reported in brain tissue purified by ultracentrifugation (Nicolau, 1939), and have been demonstrated in various tissues by fluorescence microscopy (Gerlach, 1938). Neujean (1945) claims to have demonstrated small "corpuscles" in the blood in rabic infection

The classical inclusion body is of course the Negri body, and this is described in a special section, together
bodies have been described in
lar inclusions in the vasculai
viruses French workers have described the formation of hyperchromatic intranuclear inclusions in nerve cells external to Ammon's horn in rabbits (Levaditi, Lépine, and Schoen, 1929, Lépine and Sautter, 1935). These structures are oval or round in shape and are usually found in the interior of a degenerate eosinophil nucleus They may be found in animals inoculated with phenolized vaccine (Lépine and Sautter, 1938)

The rabies virus (both strains) has been shown to be filtrable by numerous authors (e g, Remlinger, 1903 *a*, *b*, 1904 *a*, Remlinger and Riffat, 1903 *a*, *b*, Marie, 1903, Bertarelli, 1905, Neumann and Mironesco, 1913, Marie and Urbain, 1930, Sato and Kodama, 1931; Funayama, 1935).

It has been found to pass the following ordinary types of filter Berkefeld (V, N, W), Mandler; and Chamberland (L_1 and L_2). Suspensions for filtration should be prepared in broth and made dilute, otherwise difficulty may be experienced.

Levaditi and Nicolau (1923 *a*) reported that rabies virus was able to pass through collodion membranes Later, after the introduction of the collodion membrane ultrafiltration technique for the measurement of viruses, Galloway and Elford (1936) reported the size of fixed virus to lie between 100 and 150 mμ In the hands of Yaoi, Kanazawa, and Satc
0 15 μ by the same method
was slightly higher, 0 14 to c
it is probable, however, that street and fixed virus particles are of the same size, and that the reported differences are due to varying virulence of the filtrates used for inoculation of animals (Lépine and Sautter, 1941)

Cultivation

Tissue cultivation Certain preliminary attempts were made to culture the virus in association with tissue cells, but these experiments did not yield convincing

results (Noguchi, 1912, 1913; Levaditi, 1913). Stoel (1930) reported more suggestive results A number of more recent workers has shown that street and fixed virus can be cultivated in tissue culture (Kanazawa, 1936, 1937, Webster and Clow, 1936, 1937; Bernkopf and Kligler, 1937; Schultz and Williams, 1937–8, Kligler and Bernkopf, 1938 *a*, 1941 *a*, Webster, 1938, Oliveira, 1942, Plotz and Reagan, 1942; Parker and Hollender, 1945).

The virus can be propagated in Maitland's medium. It can also be grown in embryo rabbit, rat, mouse, or chick brain, and in embryo chick tissue, when serum, Tyrode, or plasma is used as the suspending fluid. Under these conditions, virus retains its infectivity for experimental animals.

Veeraraghavan (1945 *a*, *b*, 1946 *a*) has made the important claim that the virus can be grown in a cell-free medium consisting of steamed sheep-brain extract, sheep serum, glycine, and peptone; cultivation under anaerobic conditions was more favorable, growth was favored by the addition of accessory factors (see also 1947 *a*, *b*).

The egg. There has been a number of unsuccessful attempts to infect the embryo and its membranes (Schultz and Williams, 1937–8; Veeraraghavan and Philipsz, 1938, Rita, 1939, Savagnone, 1939). Others, however, have reported changes in the chorio-allantois, or invasion of the embryo without membrane changes (Peragallo, 1937, Kligler and Bernkopf, 1938 *b*, 1939; Bernkopf and Kligler, 1940; Oliveira, 1942, Sigurdsson, 1943). Chick embryos can also be inoculated intracerebrally or intra-ocularly, the infection is of a low-grade type, and the infectivity for animals may become reduced, Negri bodies are readily found (Dawson, 1939, 1941, Sigurdsson, 1943, Parker and Hollender, 1945)

Autolysis

Infected brain preserved in a
to the presence of proteolytic
and preserves infectivity for a l
Virus was recovered after 4 months from autolyzed brain kept at 18° C, but only after a few days when the brain was kept at 37° C. (Ionescu, 1943).

Rabies Toxin

That there might be such an agent as a rabies toxin was suggested many years ago (see, e.g., Remlinger, 1904 *d*), this hypothetical substance has been considered as a possible cause of neuroparalytic accident after antirabies treatment (see p. 884)

Undoubtedly, filtrates of infected nervous tissue may prove toxic to animals, but a similar property can be demonstrated in normal brain tissue (Marie, 1902). Although an acid albuminoid may be extracted from rabic brains which has a toxic effect on animals (Marie, 1912 *a*), there is no evidence for the existence of a true rabies toxin.

Diffusibility

Virus diffuses out of infected brain tissue placed in Ringer-Locke solution into the surrounding liquid (Remlinger, 1917 *d*) A similar diffusion occurs in glycerol (see p. 833).

Reaction to Physical Agents [1]

Cataphoresis Nicolau and Kopciowska (1930 *b*) found the virus to be electronegatively charged (at pH 7 4–5 8) Rabies virus (street or fixed) was also found to be electronegatively charged (pH 7 38) by workers in India, who were able to

[1] With regard to certain of the properties of *virus fixe*, it has been found more convenient to discuss these fully in the section on antirabies treatment, as most of the experiments were carried out with the express purpose of preparing a suitable vaccine

separate virus from the nervous tissue in this way (Sankaran, Iyengar, and Beer, 1934, McCarrison, Sankaran, and Beer, 1934). Working with an *oulou fato* strain, Nicolau, Mathis, and Constantinesco (1933) found this also to be negatively charged

Ultrapressure A strain of *virus fixe* was destroyed at 5,000 atmospheres (Basset *et al*, 1935).

Irradiation. Rabies virus is sensitive to the photodynamic action of methylene blue even in low concentrations of the dye, this sensitivity is not appreciably reduced by the presence of living cells (Shortt and Brooks, 1933–4, Galloway, 1934) It is destroyed by ultraviolet light (Sankaran and Beer, 1934–5 and see p 835), but not by the x-rays (Danysz, 1906). Virus is destroyed by radium emanations (Tizzoni and Bongiovanni, 1906).

Heat and cold The virus is certainly destroyed by heating to 60° to 70° C. (Babès and Lepp, 1889), and usually to 50° C. for 15 minutes (Semple, 1911). At 37° C. virus can remain active, in normal saline, for over 24 hours, and at 20° C. for about a fortnight (Semple, 1911). The virus can be preserved by freezing, and this forms a convenient method of storage (see Remlinger and Bailly, 1942 *d*).

Desiccation Street virus, of course, loses its virulence when desiccated by the Pasteur method, just as does *virus fixe* (see p 859). Bablet, Advier, and Souchard (1927) found that 7-day cords infected with street virus were virulent, 9-day cords attenuated, and 10-day cords nonvirulent. These results agree with the general experience of the reaction of fixed virus to desiccation, although it must be remembered that many strains now show a greatly increased susceptibility (see p 856). Rapid desiccation *in vacuo* preserves the virus and provided no moisture is present, virus remains active even in the presence of air (Remlinger and Bailly, 1940 *a*, *b*) Remlinger and Bailly (1938 *e*) found that desiccated brain infected with street virus survived for 2 minutes at 105° C., 3 minutes at 104° C., and 4 minutes at 103° C.

Reaction to Chemical Agents

Glycerol Generally rabies virus retains its infectivity in 50 per cent. glycerol in the refrigerator for about a year, although street virus may become inactive in a very much shorter time (Remlinger, 1923 *d*, Oliveira, 1942). Partly desiccated cords lose their remaining virulence in glycerol (see p 860).

Bablet, Advier, and Souchard (1927) found that 2-day desiccated cords (street virus) were still virulent after 20 days in glycerol, while 5- and 6-day cords were attenuated after 10 days in this agent The power to produce Negri bodies may be lost before infectivity (Levaditi, Nicolau, and Schoen, 1926). The virus usually diffuses out from the tissue into the surrounding liquid, and may even infect a neighboring healthy brain (Remlinger, 1918 *c*, *d*, 1919 *a*) Dodero (1938 *a*) recorded 2 experiments where treatment with glycerol rendered apparently inactive material virulent, similar observations have been made with herpes virus.

Ether Street virus in infected brain is destroyed in ether in 120 to 125 hours, resembling the findings with *virus fixe*. Street virus was found to be more resistant to ether than Kasauli *virus fixe* (see p 86[illegible]) [illegible]

to ether

Other chemical agents. Both strains of virus are, of course, rapidly destroyed by phenol Formol (1 per cent) also destroys street virus in about 24 hours (Gallea, 1930). Acetaldehyde (½ per cent), benzol, and furfurol all destroy rabies virus in under 3 hours (Cumming, 1914). Sublimate (0.1 per cent), potassium permanganate (0 25 per cent.), and alcohol (50–90 per cent) destroy the virus (Celli, 1886–7). Other lethal agents are soda (0 1 per cent), sodium carbonate (2 per

cent.), hydrochloric acid (0.1 per cent.) and acetic acid (Marie, 1907 *c*). Animal charcoal adsorbs and destroys the virus (Levaditi and Nicolau, 1923 *b*). Sodium ricinoleate destroys the virus (Violle and Livon, 1936; Remlinger and Bailly, 1936 *a*). Ascorbic acid has been found to inactivate fixed virus *in vitro* (Amata, 1937). Fixed virus is inactivated by mustard (Tenbroeck and Herriott, 1946). Fixed virus was found to be resistant to urea (Hoyt and Warner, 1940).

Sulfonamides. These drugs are ineffective in destroying rabies virus *in vitro* (Bruni and Buda, 1939).

Diluents. Milam (1939) examined the effect of various commonly used diluting fluids and found serum-Tyrode solution the best, while serum water was also suitable. Broth, saline, and distilled water are not to be recommended if the other fluids are available.

Reaction to Biological Agents

Rabies virus is destroyed by the lipase in pancreatic secretion, but usually resists trypsin and diastase (Hirano, 1934; Jonnesco, 1936 *b*, see also Bailly, 1945).

Bile neutralizes the rabies virus (Vallée, 1899, Galavielle and Aoust, 1901; *Lesieur*, 1906).

It was found that rabies virus placed in sacs in the peritoneal cavity of dogs and rabbits was destroyed rapidly (Remlinger, 1905 *b*).

Purification

The virus may be purified by dialyzing a glycerol extract through collodion sacs (Poor and Steinhardt, 1913), or by adsorption to kaolin in a neutral or weakly acid medium and elution in a strongly alkaline medium (Sato and Kodama, 1931). It has already been mentioned that virus can be separated from nervous tissue by cataphoresis Virus can also be purified by iso-electric precipitation of infected material (Behrens *et al.*, 1939). The need for purification can, however, be avoided by growing the virus in tissue culture (*vide supra*)

Relationship to Other Infective Agents

Although there would appear to be little or no connection between pemphigus and rabies, it has been claimed that the serum of pemphigus cases destroys rabies virus *in vitro* (Schweinburg and Wolfram, 1937).

Animals immunized against rabies showed no immunity to vaccinia, and the sera of variola cases did not neutralize rabies virus (Dodero, 1940 *a*).

No cross immunity could be demonstrated between Venezuelan equine encephalomyelitis and a fixed rabies strain of bovine origin (Kubes and Gallia, 1942).

Simultaneous Inoculation of Rabies and Other Viruses

When mice are inoculated intracerebrally with a mixture of street virus and herpes, rabies disappears after a few passages, it being suggested that herpes causes too much nerve cell destruction for Negri bodies to develop (Levaditi, 1942 *a*)

Rabies virus is similarly suppressed when mixtures of louping ill and street virus are inoculated intracerebrally in mice (Levaditi, 1942 *b*) When rabies and Theiler's virus are inoculated together, the former disappears after a few passages (Levaditi and Noury, 1944), a similar result follows inoculation with neurotropic foot-and-mouth virus (Levaditi and Noury, 1943)

Using mixtures of street virus and LGI virus, Levaditi (1942 *c*) found that both survived at least 10 passages, probably as different cells are infected; both Miya-
[illegible] e brain.
[illegible] erent nerve cells, occurs between
[illegible] (Levaditi, 1943).

CHAPTER LXXVI

THE NEGRI BODY

ALTHOUGH the pathology of rabies had been carefully studied and various lesions

these structures (e g, 1905, and see 1909 *a*) It appears that at the same time, and independently, Bosc (1903 *c*) described similar structures in rabid dogs.

The significance of these bodies was soon affirmed from all parts of the world (see Abba and Bormans, 1905, Schiffmann, 1905, Negri-Luzzani, 1905; Bertarelli, 1905, Babès, 1907, 1915; Koch, 1910, Stimson, 1910, D'Amato and Faggella, 1910) A full review of the various papers that appeared on the question of Negri bodies within the first 10 years of the discovery was published by Negri-Luzzani (1913)

THE MORPHOLOGY AND OCCURRENCE OF THE NEGRI BODY

Morphology

Shape The body is usually rounded but may vary considerably. Thus Shortt (1935–6), who has made a special study, encountered the following shapes small spherical forms, larger spherical forms, oval forms, elongated forms, a form partly broken in two with a discrete form inside, triangular forms, bulging, ameboid, or budding forms

On microscopical examination there appears to be a definite homogeneous outer covering or capsule. Muratowa (1934), studying Negri bodies in mice, however, reported that the capsule was striated

Size. The Negri bodies vary from 0 25 μ to 20 μ or even 25 μ in the longest diameter. The smallest forms tend to occur in the early stages of the infection With the progress of the disease the bodies become larger, although small forms are still visible The largest forms of Negri body have been described in cattle, especially bullocks

Staining reaction The bodies are eosinophilic, although not always very strongly so, perhaps exhibiting a purple tinge Many bodies contain basophilic granules in their substance (*vide infra*). The bodies produced by *oulou fato* strains show a special tendency to basophilism The bodies are well stained by Mann's or Laidlaw's method A number of special stains and modifications has been introduced (Faraco, 1938, Parsons, 1939, Stovall and Black, 1940, McDonald, 1944).

Position. The bodies are found intracytoplasmically in nerve cells, they often occur between the nucleus and one of the corners of the cell Quite frequently they may be found in the prolongations of the cell, where they assume an oval shape

Internal structure From the taxonomical point of view the most interesting part of the Negri body is its internal morphology, for the larger bodies frequently contain one or more granules, nuclear-like in appearance These granules are variously known as *Innerkorperchen*, *Innerformationen*, nuclei, chromatin granules, chromatoid granules, or internal bodies or structures They have been studied by numerous workers (see, e g, Negri, 1905, 1909 *a*, *b*, Maresch, 1905, Williams and Lowden, 1906, Watson, 1913, Sanfelice, 1915, Covell and Danks, 1932, Muratowa, 1934, Shortt, 1935–6, Lépine and Sautter, 1946).

These granules are basophilic, and give a weak positive reaction to other tests

[1] References are appended at the conclusion of Ch LXXIX, p 887 et seq

for chromatin. It is possible that they do, in fact, contain true nuclear material. In the smaller types of Negri body there is usually only one granule, more or less centrally situated. In the larger forms there is usually a ring of several smaller granules around a larger central one. This central body may be compact, twisted, or somewhat diffuse in appearance. The granules are round or oval in shape, and usually measure from about 0.2 μ to 0.5 μ in diameter. Certain workers have described a condensation of cytoplasm round the granules resulting in an appearance as of a cluster of spores. Further, Watson (1913) described a rupture of the wall of the Negri body with an escape of spores to all parts of the nerve cell.

The term "Negri body," strictly speaking, should refer only to bodies containing internal structures. The term "lyssa body" should be used for eosinophilic inclusions that do not show basophilic granules In actual practice the term "Negri body" is usually used in a wider sense to include "lyssa bodies."

Negri Bodies in Man

Numerous authors have recorded the presence of Negri inclusion bodies in human material, although they are not so commonly present as in certain animals They have been found most commonly in the cerebrum, but also in the bulb and cord (see Acton and Harvey, 1911; Schiemann, 1912; Negri-Luzzani, 1913; Marie and Chatelin, 1919, Gerlach, 1925; Knutti, 1929; Dwijkoff and Bogoslowskij, 1929, Bassoe and Grinker, 1930; Schukrü-Aksel, 1934). Negri bodies occur in the endoneurocytes in the sensory fibers of the trigeminal and the sympathetic nerves of the face (Manouélian, 1936 *b*, *d*). Their presence has also been noted in the suprarenal (Marinesco, 1909). Busson (1930) reported that Negri bodies were absent in over 58 per cent. of those who developed rabies despite antirabies treatment.

Negri Bodies in Animals

Negri bodies have been found in a large number of animals, infected either naturally or experimentally with street virus, their presence has been reported in the following animals

Dog. The presence of Negri bodies in the hippocampus is the standard diagnostic test for the presence of canine rabies There has been some discussion of recent years as to whether the classical conception of the hippocampus as the site of election for the formation of Negri bodies is correct. This question was brought into prominence by the paper of Thomas and Jackson (1930), who found that the hippocampus did not appear to be the site of election in experimental infection of rabbits (see also Nicolau and Kopciowska, 1932 *a*). Muratowa (1934) came to the same conclusion by using mice. Naturally it was inquired if the same state of affairs might not apply to dogs, but the classical position has been defended by Horgan and McKinnon (1937). In diagnostic work, however, it is as well to examine material from various parts of the brain before giving a negative verdict In diagnostic work it is of value first to examine the cord, as the bodies may often be found there more readily (Greene and Breazeal, 1939–40) Negri bodies may be found in the endoneurocytes of the sensory and sympathetic fibers of the face.

Rabbit The bodies are readily demonstrable in the infected rabbit. Thus, after intracranial injection they occur most profusely in Ammon's horn, but also elsewhere in the central nervous system e g, in the cerebrum, *Purkinje cells*, cells of the basal nuclei, pons, spinal cord, and spinal ganglia. Thomas and Jackson (1930) stated that the bodies often occurred more frequently in the midbrain, especially [illegible] oculomotor nucleus than in the hippocampus The bodies may be found [illegible] fibers of the face, and in the nerve [illegible] Manouélian, 1935 *b*, 1936 *b*, *d*). After intrasciatic injection the bodies are found most profusely in the spinal ganglia and the cord, and only scantily elsewhere in the central nervous system (Negri-

Luzzani, 1913). Negri bodies may not be found in the brains of small rabbits as these tend to die more quickly (Proca and Bobes, 1940).

Guinea-pig. Negri bodies are very readily found in the infected guinea-pig (see Acton and Harvey, 1911). They vary in size up to about 16 μ, and may appear partly to encircle the nucleus.

Mouse. Muratowa (1934), in particular, studied the development of Negri bodies in mice. He stated that they appeared first in the midbrain around the central canal, and only later in Ammon's horn, they contained inner structures Certain workers have introduced a diagnostic test for rabies virus based on the demonstration of Negri bodies in infected mice (Webster and Dawson, 1934–5, Webster, 1936, 1937).

Some care would appear to be necessary in the study of Negri bodies in mice, as nonspecific structures have been reported (Nicolau, Kopciowska, and Balmus,

ventricle, Ammon's horn was practically free They also described another type of nonspecific inclusion which was larger (10–12 μ), and violet- or rose-colored, these bodies were found in the upper thalamic nuclei.

Levaditi (1944) found that Negri bodies appeared suddenly in Ammon's horn on the 5th day, and suggested that they developed from small oxyphil granules normally present in the nerve cell.

Cat. Negri bodies occur in rabid cats. They should not be confused with certain small granules (0.3 μ to 0.5 μ in diameter) which may be found in the nerve cell of normal animals (Negri-Luzzani, 1905, 1913). It appears that in the brains of cats infected with street virus the nerve cells containing the bodies may show degenerative change (Babès, 1915). This is unusual, as in most animals the cell containing the Negri body is more or less normal in appearance.

Bullock. Acton and Harvey (1911) reported that in this animal large forms up to 20 μ may be found Several may occur in one cell, and they are round or oval, possibly indenting the nucleus. The bodies have also been found in other bovines, generally assuming a large size.

Other animals in which Negri bodies may occur. Negri bodies have been found in a large number of animals infected naturally or experimentally with street virus-horse (Acton and Harvey, 1911), monkey (Acton and Harvey, 1911; Negri-Luzzani, 1913), fowl (Levaditi, Nicolau, and Schoen, 1926, Remlinger and Bailly, 1929 *a*), pigeon (Remlinger and Bailly, 1929 *c*), buzzard (Remlinger and Bailly, 1932 *a*), hedgehog (Sanfelice, 1915, Jonnesco, 1932 *a*), Chinese hamster (Yen, 1936 *a*), spermophiles (Jonnesco, 1932 *a*), capybara (Vianna, 1929), tortoise (Remlinger and Bailly, 1932 *a*), jackal (Acton and Harvey, 1911) and wolf, lion (Manouélian and Viala, 1922), goat (Acton and Harvey, 1911, Negri-Luzzani, 1913), pig (Negri-Luzzani, 1913), bat, mongoose.

Tissues in which Negri bodies may be found in animals.

Nervous system Negri bodies occur most commonly in the ganglion cells of the central nervous system, including the spinal ganglia They may also be found in the endoneurocytes of the sensory and sympathetic fibers of the face, and in the sympathetic ganglia (Manouélian, 1936 *b*, *d*), they may occur in bulbar nerves (Manouélian, 1936 *c*). They may, however, be found in various other parts of the body.

Salivary glands. Negri bodies may be found in the intraglandular ganglionic nerve cells in dogs, but not in the acini or the excretory canals (see Stefanescu, 1907, Manouélian, 1914) Bodies also occur in ganglion cells just beneath the lingual mucosa

Manouélian has stressed the importance of finding Negri bodies in the nerve cells of the salivary glands and mucosa of the tongue as affording the key to the

way in which the saliva becomes infected with virus (see, e.g., Manouélian and Viala, 1924, 1926, 1927, 1928 *b*; Manouélian, 1935 *a*, *b*).

Adrenal glands. After injection of virus into the adrenal glands very small Negri bodies were found locally (Levaditi and Schoen, 1935 *a*).

Cornea. The fact that Negri bodies may quite readily be demonstrated in the rabbit's cornea has only been pointed out comparatively recently by Levaditi and his coworkers Thus, Negri bodies appear in the corneal epithelium after inoculation of virus by scarification, or intra-ocular or intracerebral injection (Levaditi, Schoen, and Levaditi, 1934 *b*, *c*, Levaditi and Schoen, 1933, 1935 *a*, *c*, 1936 *a*). Negri bodies will develop in corneal cells undergoing regeneration after the application of croton oil (Levaditi and Schoen, 1936 *b*).

After intra-ocular injection small Negri bodies may be found in the retina (Levaditi, Schoen, and Levaditi, 1934 *a*).

In corneal infection the Negri bodies are usually small, measuring up to 4 μ, and are not very numerous in the initial stages, with the progress of infection they become more numerous. After corneal inoculation they appear contralaterally also. Corneal inoculation of guinea-pigs, cats, dogs, and monkeys does not produce Negri bodies, although they may be found occasionally in mice (Levaditi, Schoen, and Levaditi, 1934 *b*; Levaditi and Schoen, 1935 *a*).

Other organs. It appears that the cornea is the only epithelial tissue in which Negri bodies can develop. Thus, bodies were not found locally after injection of the rabbit's conjunctival, nasal, lingual, tracheobronchial, or intestinal mucosae, nor were Negri bodies found locally after injection of the parotid, testis, ovary, or skin (Levaditi, Schoen, and Levaditi, 1934 *c*, Levaditi and Schoen, 1935 *a*). It has, of course, already been mentioned that Manouélian found Negri bodies in the nerve cells beneath the lingual and buccal mucosae in animals.

Negri Bodies in Artificial Culture

Peragallo (1937) found Negri bodies in the chorio-allantois of the chick embryo They have been found in the brain and cords of chick embryos inoculated intracerebrally (Dawson, 1939) They do not seem to have been studied in tissue cultures prepared by the slide or Carrel techniques.

Negri Body Counts

An estimate of the extent of "parasitization" by Negri bodies can be obtained by counting 100 neurons and noting the number of bodies contained therein (see, e g, Nicolau and Kopciowska, 1933).

NEGRI BODIES PRODUCED BY *VIRUS FIXE*

It is generally held that *virus fixe* does not produce Negri bodies nearly so readily as does street virus, this property usually becoming lost after 25 to 45 passages (Schiffmann, 1905–6) However, Negri bodies may, in certain cases, be quite easily found. Thus, various authors have found Negri bodies in fixed virus infections of the rabbit (Manouélian, 1906, 1912, Ferré and Bonnard, 1908, Da Silva, 1927, Levaditi, Schoen, and Merger, 1932 *a*, Nicolau and Kopciowska, 1932 *a*, 1933, Lépine and Sautter, 1935) They may be found in infection with fixed *oulou fato* virus (Nicolau, Mathis, and Constantinesco, 1933), and Sassari virus (Lépine and Sautter, 1936) They can be found in animals infected with the highly active virus of *mal de caderas* (Remlinger and Bailly, 1931 *a*) These bodies are usually small (up to 7 μ), round or oval, and may possess an internal structure, although this is unusual. They may occur in Ammon's horn, but are sometimes said to be more profuse in the bulb (especially in the oculomotor nucleus) than elsewhere, this latter is important, as it may explain the failure of many workers to detect these bodies They may also occur in fixed virus infections of the following animals dog (Manouélian, 1912, Palawandow *et al.*, 1935), mice (Palawandow *et al.*), hedge-

hog (Palawandow *et al*), rat (Palawandow *et al*), guinea-pig (Palawandow *et al*), chameleon (Acton and Harvey, 1911).

Lentz bodies This is a convenient place to mention the bodies first described by Lentz (1909) and which go by his name. These structures measure about 10 μ in diameter; they occur extracellularly, being found between the ganglion cells in the central nervous system of rabbits injected with *virus fixe* They are eosinophilic and contain blue *Innerformationen* Similar bodies occur in "nervous distemper" of various animals.

NEGRIGENESIS OF DIFFERENT STRAINS OF VIRUS

There may be a certain amount of difference in the readiness with which various strains produce Negri bodies, that is to say, in their powers of negrigenesis (see Levaditi, Nicolau, and Schoen, 1926) Thus, working with the cornea Levaditi and Schoen (1935 *b*) found considerable variation between strains of street virus in this respect. It has been noted that the strains of street virus which do not readily produce Negri bodies are those which become fixed most quickly (*virus de rue renforcé*), and then do not produce inclusion bodies (Levaditi, Nicolau, and Schoen, 1924 *e*).

The Tunis strain of *virus fixe* was found to produce Negri bodies quite readily on intracerebral injection of rabbits, while the Tangier and Paris strains did not, ... 1935 *a, d*). ... the pro- ... passaged ... again to a certain extent their capacity for producing Negri bodies (Kopciowska, 1935 *a, b*, Nicolau and Kopciowska, 1935 *b*, 1936).

THE SPECIFICITY OF THE NEGRI BODY

There is world-wide unanimity on the specificity of the Negri body. That is to say, the occurrence of eosinophilic inclusions (usually with *Innerformationen*) in the nerve cells signifies the presence of a rabic infection. The appearance of the fully developed Negri body is unlikely to be mistaken for anything else With regard to the simpler lyssa body, however, various degenerative changes may simulate this homogeneous eosinophilic structure

There remain to be recorded some miscellaneous observations on specificity, none of these, however, offers any challenge to the trust rightly reposing in the specificity of the Negri body, being concerned mainly with structures that may be mistaken for lyssa bodies Thus, as mentioned above, lyssa-like bodies may be found normally in cats and mice and probably other animals as well Further, it was found that on rare occasions injections of Russell's viper venom produced lyssa-like bodies in the fascia dentata of guinea-pigs (Acton and Harvey, 1911). Also, rabbits injected with *B pyocyaneus* cultures might on occasions show lyssa-like bodies in their nerve cells (Acton and Harvey) Steinhardt *et al.* (1912) were able to produce small lyssa-like bodies by incuba- ... plasma Shortt and Lahiri (1934) produced ... by prolonged physiological stimulation of ... somewhat resembling Negri bodies may occur in the brain in canine distemper with encephalitis (Rifkin *et al*, 1945)

THE NATURE OF THE NEGRI BODY

ward much experimental data for the belief that normal cell constituents enter largely or entirely into the formation of the Negri body. The Negri body has been tested by almost all the usual methods, except, so far as we can discover, by micromanipulation The application of this technique (as used in other virus infections, see Ch X) should solve the problem of whether the body is purely degenerative or contains a living agent.

Experimental Observations

(*a*) *Microscopic.* The morphology of the body in ordinary stained preparations has already been sufficiently described. Darkground examination of unstained bodies shows that their structure is definitely granular and not homogeneous, the granules are not motile (see, e.g., Covell and Danks, 1932). Levaditi and Mezger (1933) studied Negri bodies (in mice) darkground, under a magnification of 1,800 diameters, and stated that the bodies (pansporoblasts) contained 5 or more cysts

(*b*) *Infra-red photography.* Guardrabassi (1935) examined Negri bodies in photographs taken by infra-red light, and found that they had a granular structure, even to the very periphery.

(*c*) *Vital staining.* Vital staining has been carried out by Covell and Danks (1932). According to these authors Negri bodies take up brilliant cresyl blue, Bremen blue, and Paris blue, the chromatoid granules and central mass appearing bluish-violet and vacuolated With Janus green B the chromatoid granules stain green and remain so after the color of the mitochondria has faded.

(*d*) *Tests for the presence of normal cell constituents*· (1) *Chromatin.* Negri bodies, as a whole, give a negative Feulgen reaction (Paul and Schweinburg, 1926), although a faint positive test many be given by the chromatoid granules (Covell and Danks, 1932). Similar results are obtained by Millon's and MacCallum's tests (*Covell and Danks*). *This finding suggests that only the chromatoid granules contain* any nuclear chromatin (see also Lépine and Sautter, 1946).

(2) *Golgi apparatus and mitochondria.* Negri bodies do not react to stains for the Golgi apparatus (Fañanás, 1922, Levaditi, Schoen, and Mezger, 1932 *b*), nor do they react to stains for mitochondria (Schiffmann, 1905–6; Levaditi, Schoen, and Mezger, 1932 *b*). Here one may mention [illegible] *been* found in the ganglion cells in rabies (e.g., [illegible] bably of mitochondrial origin and not lyssa bo[illegible] e cell in which Negri bodies are found may show degenerative changes in the mitochondria and Golgi apparatus, but these changes are more likely to be the result than the cause of the inclusion (Covell and Danks, 1932)

(3) *Neurofibrillar network.* Goodpasture (1925) found that a degenerative change in the neurofibrillar apparatus of the ganglion cells might result in the production of bodies identical with lyssa bodies.

(4) *The Nissl substance and nuclear chromatin* Covell and Danks (1932) believed that the virus produces chromatolysis, with an accompanying alteration in the Nissl substance (see also Mackenzie, 1897, Cowdry, 1928). They suggest that iron-containing basophilic nuclear material is extruded into the cytoplasm where it is eventually converted into the oxyphil matrix of the Negri body In the center basophilic material remains unaltered as the *Innerformationen*

Another line of approach to the problem of the Negri body has been to *infect* animals with virus and to kill them at varying periods thereafter, and study the Nissl substance Nicolau and Kopciowska (1934 *a*) injected rabbits intrasciatically with street virus They found that Negri bodies appeared in the neurons of the corresponding ganglia from the 7th day onward. During these 7 days of incubation they found various changes

(*a*) The Nissl bodies agglutinated, eventually to form chromophil masses of irregular appearance.

(*b*) From these masses a number of regular basophilic spherical bodies was formed

(*c*) Next a small red dot appeared in the center of these bodies, the redness spread, and eventually small Negri (lyssa) bodies were formed Oxyphil material was further laid down and these smaller bodies might fuse to form a larger.

(*d*) The cells with the best-formed Negri bodies contained no Nissl bodies. [illegible] - those cells normally richest [illegible] idies, e g, cells in the spinal

From this work they concluded that the Negri body was the expression of the defence of the cell. A successful defence meant preservation of the cell with a Negri body contained therein Unsuccessful defence meant possible destruction, without the presence of any Negri body.

(*e*) *Micro-incineration* Micro-incineration studies were carried out by Covell and Danks (1932), [illegible] injection with street [illegible] white in color, wh [illegible] iron. There was no evidence for the presence of a membrane, nor for the presence of individual parasites in the body. If the internal structures were nuclear, ash-free areas would have been expected, but none such occurred In the cells containing [illegible]

Theoretical Considerations

(*a*) *The Negri body as a protozoon* It was only natural that in the early days, workers should believe the Negri bodies to be protozoal organisms (see Negri, 1903 *a*, *b*, 1909 *a*, *b*, Di Vestea, 1904, Volpino, 1905–6, Williams and Lowden, 1906, Calkins, 1909) To them the appearance of the internal structures was very suggestive of a nucleus, and the bodies appeared to be of the same nature as malarial or other protozoal organisms Calkins gave the name *Neurocytes hydrophobiae* to the rabies organism

More recently the protozoal theory has been upheld by Levaditi and his co- [illegible]

are known as spores, these pass along the nerves from the site of the wound and reach the central nervous system. Second, arrived at the central nervous system they undergo an intracellular proliferation to form the pansporoblast or Negri body The pansporoblast consists of an envelope formed from the cytoplasm of the nerve cell, and contains a number of spores, each with chromatin material. The development of this pansporoblast depends on the virus and on the host. Thus, if the virus is virulent it may destroy the nerve cell before a pansporoblast can form For instance, in *virus fixe* infection the virus is said to be of such virulence that these pansporoblasts are not usually found If *virus fixe* is injected into a rabbit already infected with street virus, then Negri bodies occur only rarely. *Virus fixe* seems to be able to prevent the pansporoblast stage from occurring.

Levaditi believes that the Negri body is one stage of a protozoon analogous to *Encephalitozoon cuniculi*, or *Glugea lophii*, both of which protozoa occur in brain tissue He has given the name *Glugea lyssae* to the rabies organism. Only one phase, that of the Negri body (pansporoblast), is visible, in the other phase (spores) the organism is invisible and filtrable.

Of somewhat similar implication is the term *Encephalitozoon rabiei* applied to the rabies organism by Manouélian and Viala (1924). These workers have described small fusiform or pyriform bodies measuring 1 μ to 2 μ in diameter, which are said to contain chromatin granules and to be surrounded by a membrane. Variable numbers of bodies may occur inside cells, and they may fuse to form the larger Negri body. The bodies are held to represent a spore-like phase of a protozoon.

Veeraraghavan (1944) has found what he takes to be a protozoon in the nerve cells in the midbrain in guinea-pigs, also in dogs and jackals. Various forms of the parasite are described and it appears to be filtrable. It is possible, he holds, that the Negri body is a stage in the life cycle of this parasite.

Levaditi's theory is certainly most attractive and ingenious. In particular it obviates the necessity for always finding Negri bodies in sites where the virus can be shown to exist; because, under certain circumstances, only the filtrable phase is present, he suggests; the pansporoblast phase is only facultative—it need not always occur.

It is difficult, however, to see how this theory can be regarded as anything but unproved. Although there is little or no evidence actually against the theory, there is none that proves that the rabies virus is a protozoon. The micro-incineration studies of Covell and Danks (1932) certainly do not support the protozoal theory, they were unable to find any evidence of a definite cyst wall or membrane to the Negri body, or of a protozoal nucleus. The delegates attending the First International Conference in Paris in 1927, after examining preparations by Levaditi and Manouélian, were unable to decide whether the Negri body represented a living organism or was merely of degenerative nature. During the past 10 years, the observations that have been brought forward have tended more to emphasize the rôle of normal cell constituents in the formation of the Negri body.

(*b*) *The Negri body as a colony of virus particles.* The Guarnieri body of variola-vaccinia, the Bollinger body of fowl-pox, and the inclusion body of molluscum contagiosum all consist of a mass of elementary bodies held together as if in a colony. The question naturally arises has the Negri body the same type of structure?

There is certainly evidence that the Negri body contains granules, and even in the early days it was suggested that it was a chlamydozoon containing elementary bodies in a sticky matrix (Volpino, 1905–6, Prowazek, 1907, Babès, 1907, Lipschutz, 1919). More recently the granularity of the Negri body has been confirmed by darkground examination and infra-red photography. Some difficulty arises in con-
nec
boc
virt
of

(*c*) *The Negri body as a product of the cell.* It has, of course, been suggested by histologists from the earliest days that the Negri body is a purely degenerative structure formed from the cell constituents. That the degeneration must be of rather a particular and specific type was admitted, for the nerve cell containing the body usually appears comparatively little damaged. Thus, it has been suggested that the Negri body is derived from the following structures.

1. *The nucleolus.* This theory was advanced by Acton and Harvey (1911, 1912–13), who regarded Negri bodies as the result of an interaction between extruded nucleoli and the cytoplasm. They found that the nucleoli in the nerve cells of rabid animals stained abnormally, and were often fragmented. These fragments, they suggested, were discharged into the cytoplasm to constitute the iron-reacting granules in the Negri bodies. This theory is somewhat similar to that expressed more recently by Covell and Danks, and already alluded to, in which they suggest that nuclear chromatin is extruded and undergoes oxyphil degeneration.

2. *Neurofibrils.* It has already been mentioned that Goodpasture (1925) found

that a degenerative change occurred in the neurofibrillary network of the ganglion cells. This change produced eosinophilic Negri-like bodies without inner structures This theory would serve to explain the formation of lyssa bodies but not of true Negri bodies

(3) *Nissl substance and nuclear chromatin.* As mentioned, a number of workers has stressed the rôle of the Nissl substance. It appears that lyssa-like bodies may develop by oxyphil degeneration of this material. Others suggest that basophil

because if the oxyphil change begins at the periphery and spreads inwards, one would reasonably expect the center of some of the larger bodies to be still basophil and unaffected by the change. This theory is the only one of this type that can reasonably explain the *Innerformationen* (Black, 1940).

Conclusions

manipulation, and to inject such a structure into an animal It is possible that electron microscopy may prove of value.

CHAPTER LXXVII

IMMUNITY MECHANISMS IN EXPERIMENTAL RABIES

A. NATURAL IMMUNITY

A NUMBER of species of animals is quite insusceptible to infection with rabies virus E , an occasional resistant animal n 38 *b*; Jonnesco, 1934 *a*, 1936 *a*, J whether the serum of animals naturally resistant to rabies is rabicidal. Thus Kondo (1922) reported that the sera of two naturally refractory dogs were rabicidal. Phisalix (1926) found the serum of the adult hedgehog to be rabicidal, but Jonnesco (1927 *a*) could not confirm this point. The serum of vipers and eels was found to be rabicidal (Remlinger and Bailly, 1928 *a*).

It is not clear whether the offspring of immune mothers are immune or not Remlinger (1908 *c*) claimed that hereditary immunity does occur, but Babès and Talasescu (1894) could not demonstrate any such resistance.

B. ACTIVE ACQUIRED IMMUNITY

Animals become resistant to rabies on recovery from infection with street virus, but this is a rare event, and of little practical importance. A considerable amount of work has been carried out on the development of active immunity by vaccination, prior to infection ("challenge") with a test inoculum of live virus.

Species of Animal Immunized and Route of Injection

Of the laboratory animals, dogs, rabbits, monkeys, guinea-pigs, rats, and mice have all been rendered refractory by vaccination with live or chemical vaccines to subsequent challenge doses of living virus. Many of the early workers claimed to have demonstrated this acquisition of immunity, although it must be said that their experiments were not always well controlled, the state of immunity was not always of a high order and could usually be broken down by a sufficiently large challenge dose, especially given intracerebrally or intra-ocularly (Pasteur *et al*, 1884, Galtier, 1881, Bardach, 1887 *a*, Roux and Nocard, 1888, Roux, 1888 *b*, Protopopoff, 1888).

Larger animals such as goats, sheep, and horses have also been immunized, mainly with a view to producing antirabies serum

The important question of prophylactic immunization of dogs is discussed in a separate section below

Immunizing injections can be given subcutaneously, intravenously, intraperitoneally (Remlinger, 1908 *b*, Lieou, 1940), percutaneously (Remlinger and Bailly, 1927 *d*, 1928 *a*, de Georges, 1926), or rectally (Remlinger, 1907 *b*) Some have claimed that immunizing injections can be given intracranially (Phisalix, 1926, Tzekhnovitzer and Goldenberg, 1930), but others disagree (Remlinger and Bailly, 1928 *c*, Loeffler and Schweinburg, 1930–1) Intraspinal injections of irradiated virus were found to immunize rabbits (Kasahara and Sha-Shi-Nan, 1940)

Source of Vaccine

Numerous preparations have been used to provoke active immunity.

(*a*) *Living*, or attenuated, *virus fixe* can be injected intraperitoneally, sub- or intra-cutaneously (see, e g, Hoegyes, 1887, 1889 *a*, *b*, *c*, Fermi, 1908, Stuart and

[1] References are appended at the conclusion of Ch LXXIX, p 887 *et seq*

Krikorian, 1932 *a*, Shortt *et al*, 1934–5, Webster, 1939 *b*, Casals and Webster, 1940). Owing to the risk of death, and the difficulty of giving large quantities, this method is not widely used, although resistance can be stimulated by live virus, especially against a peripheral challenge.

Webster (1939 *b*) found that mice were immunized with the Hoegyes and Harris live vaccines within 10 days to withstand 100 intracerebral lethal doses, and that this resistance persisted for at least 9 months. In experiments with dogs Shortt *et al* (1934–5) found that the most effective method of protection was to give live virus after a course of carbolized vaccine.

(*b*) *Killed vaccines* of various types have been used. Certain earlier workers did not carry out adequate controls and others probably used relatively inert material Provided, however, that the vaccine contains a sufficient quantity of virus, and that the strain is fully antigenic, a satisfactory state of immunity can be induced in dogs, monkeys, rabbits, guinea-pigs, and mice by phenolized, etherized, chloroformized, and formolized vaccines, there is evidence that the chloroform-treated vaccines are somewhat superior (see, e g, Remlinger, 1919 *c*, Gloster *et al*, 1929–30, Kelser, 1930, Tzekhnovitzer and Goldenberg, 1930, Stuart and Krikorian, 1932 *a*, Okuwada, 1933, Shortt *et al*, 1934, 1937, Jacotot, 1938, van Stockum, 1938, 1941; Boecker, 1938–9, Lépine and Sautter, 1939, Webster, 1939 *b*, Johnson and Leach, 1940 *b*, 1942, Leach and Johnson, 1940 *b*, *c*, 1942, Webster and Casals, 1941, 1942 *a*, Veeraraghavan, 1946 *b*).

Alumina gel may be added to formolized virus (Jacotot, 1947).

Guinea-pigs have been immunized to withstand intramuscular injection of test virus by 2 injections of brain inactivated with mustard (Tenbroeck and Herriott, 1946).

Injections are usually given repeatedly, as large doses are needed, and by the subcutaneous or preferably the intraperitoneal route. Resistance is usually sufficient to withstand an intracranial test dose. It should be realized that the doses used have usually been very large, monkeys for example receiving doses similar to those given to human beings Webster (1939 *b*) found that a phenolized and a chloroformized vaccine had to be used in mice in a dose approximating 5 times that advocated per gm of body weight for man

(*c*) Dogs, rabbits, guinea-pigs and sheep have been immunized by *mixtures of virus and antiserum*, neutral or otherwise (Marie, 1902; Remlinger, 1904 *f*, 1906 *e*) Rabbits have been immunized by neutral mixtures of hedgehog (naturally immune) serum and *virus fixe* (Phisalix, 1926) Shortt *et al* (1934–5), however, did not obtain definite evidence of the value of serum combined with virus

(*d*) Virus grown in *tissue cultures* can be used to immunize animals either in its live state, formolized, or when inactivated by ultraviolet light (Hodes *et al*, 1937, 1940, Webster, 1937, 1938, Kligler and Bernkopf, 1938 *a*, 1941 *b*, Webster and Casals, 1941) Webster (1938) prepared the vaccine as follows 4 c c of 10 per cent monkey serum in Tyrode + 0 02 c c of minced mouse embryo brain is inoculated with 1 c c of a 1 100 dilution of infected mouse brain, the cultures are incubated at 37° C for 3–4 days in a 50 c c Erlenmeyer flask, passage is performed with the supernatant obtained after centrifugation. Veeraraghavan (1946 *b*) claimed that his "cell-free" culture virus immunized guinea-pigs against fixed virus injected subdurally, and rabbits against street virus injected in the neck

(*e*) The principle of *inactivation by exposure to U-V light* can also be extended to infected brain tissue (Webster and Casals, 1940 *a*, 1941, 1942 *a*, *b*, Levinson *et al*, 1944) Such vaccines are considerably more potent than tissue cultures or chloroformized and phenolized vaccines, but must not be irradiated for too long, or antigenicity is decreased They appear to contain inactivated virus The method adopted by Webster and Casals (1942 *a*) was as follows Two-month old beagle dogs were inoculated intracerebrally with infected mouse brain and when prostrate their brains were removed, weighed, triturated and diluted with buffered distilled

water to make a 5 per cent suspension, which was centrifuged. To be effective this supernatant had to titer 330,000 or more mouse intracerebral doses per c.c. The supernatant was rendered avirulent by exposure to U-V light for 35 minutes. Intraperitoneal injection of this vaccine would protect mice against 10,000 MLD (as compared with a chloroformized vaccine—1000 MLD). Of 35 dogs given 30–40 c.c. of this irradiated vaccine in one dose, all were protected save one, and when the vaccine was concentrated sixfold all of 24 animals were protected. Mortality in the unvaccinated control dogs was 84 per cent. Habel (1947), using the Levinson type of lamp, has produced a vaccine considerably more potent than that used by Webster. Later he introduced an alternative lamp (see Habel and Sockrider, 1947)

(*f*) *Virus inactivated by methylene blue* is still antigenic (Galloway, 1934), but is unlikely to be sufficiently active for use in antirabies treatment (Shortt and Brooks, 1934–5). It is probable that such vaccines are ineffective unless some live virus remains.

The Effect of Age on Development of Immunity

W-Swiss mice of 60 or more days old were more readily immunized than 20-day or younger mice; thus, 1600 doses injected peripherally immunized 60-day-old mice against 100 or more doses given intracerebrally, but 20-day mice against only 10 or less doses (Casals, 1940 *b*, Casals and Webster, 1940).

Technical Methods in Testing the Degree of Immunity

It has been usual to challenge immunized animals after their course of vaccine by injection of street or fixed virus intracerebrally, intra-ocularly, subcutaneously, or intramuscularly. Various workers, using less effective vaccines, have experienced difficulty in immunizing animals sufficiently to withstand intracerebral or intra-ocular injections of test virus. It was generally held that the intracranial test was too severe. Newer and more potent vaccines may, however, immunize sufficiently for an intracranial test dose to be withstood. It has been found considerably easier, however, to protect against a peripheral injection of test virus (see Webster, 1939 *a*, 1942).

In tests for the immunizing potency of vaccines it is always desirable to inject the test dose of virus in such a way that as nearly as possible 100 per cent. of the control unvaccinated animals develop rabies Unless injected intracerebrally or intra-ocularly, however, it is very difficult to secure infection of more than 50–75 per cent of controls. It is also desirable to use an accurately titrated amount of test virus, and for this purpose it is now usual to employ mice. Albino rats were recommended by Cornwall and Beer (1925–6 *c*). Various methods have been introduced in recent years for assaying the immunizing potency of antirabies vaccines.

1. Webster's mouse immunity test

Webster (1939 *b*, 1940, 1941) introduced a simple test carried out as follows

Dilute the vaccine 1/10 and use 1/8th of the stated dose (i e, 1/80th) Set aside 16 3-week-old mice for the test and a similar number as controls In the case of canine vaccines, 1 dose is given intraperitoneally to each test mouse When testing human vaccines, the 16 mice are injected intraperitoneally for 3–6 days Three weeks after the first injection of vaccine, the 16 test mice are divided into 4 lots and tested intracerebrally with 1, 10, 100, and 1000 MLD. The controls are treated likewise Sometimes the challenge dose is given intramuscularly in the gastrocnemius muscle, using from 2–32 MLD in doubling dilutions This test is more sensitive and detects relatively weak immunizing capacity. The test and control mice are examined for 60 days

Webster regarded the mouse immunity test as of considerable value in indicating the immunizing efficiency of antirabies vaccines Remlinger and Bailly (1943 *c*, *d*), on the other hand, question whether mice are really suitable for such tests, and suggest that they are unduly susceptible to rabic infection, virus probably not spreading to the nervous system by means of nerve paths, as occurs in man and larger laboratory animals

2. *Wyckoff's method*

The following method has been used by Wyckoff (1940-1, Wyckoff and Beck, 1940, Wyckoff and Tesar, 1941). Ten 3-week-old mice are vaccinated daily for 6 days with 0 6 c c of a 1/9 dilution of vaccine given intraperitoneally. Six days later, 5 mice are injected intracerebrally with 100 MLD, and 5 mice with 1000 MLD of homologous fixed virus The result is assessed 2 weeks later

3 *Habel's method.*

Habel (1940 a) uses 30 Swiss mice, all of one sex (preferably female), and administers 0 25 c c of vaccine diluted to contain 0 5 per cent brain tissue (i e, usually 1/10) intraperitoneally every 2nd day, giving 6 doses in all, 18 controls are needed Fourteen days from the first dose of vaccine, the challenge dose is given to the immunized animals The test virus consists of fresh passage brain tissue, and is titrated by dividing the controls into 3 groups and injecting 0 03 c c. of 10^{-5} to 10^{-7} dilution intracerebrally. The immunized mice are divided into 5 groups, and injected intracerebrally with 0 03 c c. of 10^{-1} to 10^{-5} dilutions The mice are observed for 21 days The MLD is the highest dilution causing death from rabies in at least 3/6 controls The end-point of the immunity in the vaccinated mice is the lowest dilution of the test virus which causes at least 3/6 to survive The number of MLD protected against can be determined easily by the number of times the dilution giving the end-point in vaccinated mice is more concentrated than in the controls When the end-point is irregular, the 50 per cent end-point should be calculated by Reed and Muench's (1938) method

This technique is applicable to all types of killed virus vaccine When testing live or attenuated viruses the 6 intraperitoneal doses must be graded Habel considered that the minimum requirement of an efficient vaccine was that it should protect against at least 1000 MLD Habel and Wright (1948) have recently described improvements in this method of assay, designed to give more consistent results

4. *Methods using dogs*

Dogs have been extensively used in this type of work. For example, they have been challenged after 4 weeks with street virus injected in the masseters, under these conditions only 50-60 per cent of unvaccinated controls die of rabies (Johnson and Leach, 1940 *b*, 1942, Leach and Johnson, 1940 *b*, *c*, 1942)

Webster and Casals (1940 *b*) have recommended the following test Beagle dogs, 4-6 months old, are immunized with the vaccine, as required Three weeks later they are challenged by an injection into the neck muscles on either side of 0 25 c c of varying dilutions of a passage strain, 3 groups of animals receiving 1, 10, or 100 lethal doses Suitable numbers of controls are similarly injected The test and control dogs are observed for 2 to 5 months

Miscellaneous Observations

The effect of alcohol on development of immunity It has been stated that alcohol-treated animals do not acquire immunity (Deléarde, 1897) Remlinger and Bailly (1932 *a*), however, found no difference in the resistance of normal and alcohol-treated groups

Nonspecific results of vaccination These results were summarized by Cruveilhier, Nicolau, and Kopciowska (1935, see also 1931, and Nicolau, Cruveilhier, and Kopciowska, 1932)

1 Treatment raised the *Bact typhosum* agglutinin titer of a rabbit previously immunized against this organism
2 The hemolytic power of the serum was likewise increased in rabbits previously injected with sheep's red cells
3 The general health of the animal was improved
4 Antirabies treatment applied to lactating rabbits carrying a Shope's tumor caused it to disappear (Haguenau, Cruveilhier, and Viala, 1937)

There has been some discussion whether long courses of antirabies treatment render animals more susceptible to subsequent injections of virus Loeffler and

Schweinburg (1930) claimed that this was so, but Remlinger has disagreed (Remlinger *et al.*, 1931 *b*, Remlinger and Bailly, 1931 *a*)

Histological reaction in vaccinated animals. Immunization by the desiccated cord method was found to produce definite lesions in the central nervous system (Nicolau, Cruveilhier, and Kopciowska, 1931 *a*, *b*; Cruveilhier, Nicolau, and Kopciowska, 1935). These reactions have been attributed to a mild infection, the virus is only attenuated and probably the reaction is one of defence. Some cellular infiltration may be found in the meninges In the cerebral cortex there are areas of mononuclear infiltration and microglial reaction. Very marked satellitosis of nerve cells occurs in the mesencephalon and diencephalon. In the cord, the posterior horn is infiltrated with mononuclear cells, satellitosis may be seen. The Nissl bodies may be degerate and agglomerated in large masses. In the spinal ganglia a parenchymatous infiltration of mononuclears and a proliferation of capsular cells are usually present. Lépine and Sautter (1938) have reported that nuclear inclusions (see p. 831) develop in the brain after injection of phenolized virus; this they attribute to the presence of living virus in their vaccine.

The reticulo-endothelial system in acquired immunity. Immunity can be acquired by splenectomized dogs (Plantureux, 1932). A previously acquired immunity can, however, be abolished by blockade with India ink (Loeffler and Schweinburg, 1933–4). Further, Loeffler and Schweinburg (1932 *a*) have shown that the serum of animals blockaded with India ink and vaccinated is less virucidal than that of unblockaded animals, in addition, these animals are less protected against reinfection than unblockaded animals. The reticulo-endothelial system would seem, therefore, to play a definite rôle in resistance to infection

C. PROPHYLACTIC ANTIRABIES TREATMENT OF ANIMALS

In various parts of the world where rabies is endemic, prophylactic immunization of dogs and sometimes other animals has been carried out, in an attempt to limit the spread of the disease (Remlinger, 1919 *a*, Plantureux, 1926 *a*, Vallée, 1927, Remlinger and Bailly, 1932 *a*, 1934 *c*; Balozet, 1938 *a*, *b*, Gautier, 1940) The following vaccines have been used

(*a*) Living *virus fixe* vaccines (Roux and Nocard, 1888, Galtier, 1897, Schnurer, 1905, Remlinger, 1921, Jonesco, 1930 *b*)
(*b*) Hoegyes' vaccine (Aujzesky, 1922)
(*c*) Desiccated cords (Babès and Bobes, 1912)
(*d*) Finzi's vaccine (Vallée, 1927)
(*e*) Marie's vaccine (Rodet and Galavielle, 1900, Marie, 1905 *c*, Remlinger, 1905 *g*, 1909 *b*, Shortt *et al*, 1934–5)
(*f*) Miessner's (1912) vaccine
(*g*) Oil-emulsion vaccines (Botofogo Gonsalves, 1924, 1926 *a*, *b*)

More use has, however, been made of the following methods

(*h*) Etherized vaccines (Remlinger, 1918 *a*, 1919 *a*, 1925 *c*, Bailly, 1926, Remlinger and Bailly, 1930 *f*, 1932 *a*)
(*i*) Chloroformized vaccines (Kelser, 1930, Schoening, 1930, Barnes *et al*, 1934; Webster, 1939 *b*, 1940, Leach and Johnson, 1940 *c*, Webster and Casals, 1942 *a*)
(*j*) Formolized vaccines (Konieff and Ramsine, 1928, Plantureux, 1935, 1938)
(*k*) Phenolized vaccines, attenuated or killed (Umeno and Doi, 1921, Kondo, 1922, Kitt, 1925, Velu *et al*, 1926, 1928, Plantureux, 1926 *a*, *d*, Legezynski and Markowski, 1928 *a*, Markowski and Legezynski, 1928 *a*, Dos Santos, 1929, Schoening, 1925, 1928, 1930, 1931)
(*l*) Irradiated vaccines are highly effective immunizing agents (see p 845), Webster and Casals, 1942 *a*).

Vaccines are usually given in one dose subcutaneously or preferably intraperitoneally. It is very questionable how much resistance has been induced by many of

the above mentioned workers, for it appears that a considerable number of vaccines available commercially has been possessed of only very slight immunizing activity (Johnson and Leach, 1940 *b*, L. T. Webster, 1939 *b*, 1940, L. T. Webster and Casals, 1940 *b*, 1942 *a*, W. J. Webster *et al*, 1940; Wyckoff and Beck, 1940, Wyckoff and Tesar, 1941). Thus L. T. Webster (1939 *b*, 1940) tested a considerable number of phenolized preparations, and found that none immunized mice against a subsequent intracerebral challenge dose of 1 MLD; chloroformized vaccines, however, im- [illegible] -se recommended, proportionately, [illegible] phenolized vaccines were found [illegible] vaccines produced a significant degree of resistance, especially if given in 10 c c. amounts intraperitoneally (see also Webster and Casals, 1940 *b*, 1942 *a*, Leach and Johnson, 1940 *c*).

There is considerable doubt about the effect of mass vaccination of dogs on the incidence of rabies, and it would appear from what has been said above, that much of the vaccination work done in the past must have been completely ineffective. Provided a potent chloroformized or newer irradiated type of vaccine is used, in doses proved experimentally to be antigenic, it would seem reasonable to expect some decrease in the incidence of rabies in countries with large dog populations

Johnson in Alabama has found that a significant degree of immunity can be conferred on dogs against an intramuscular challenge of street virus one year later; a single subcutaneous injection of 5 c c. of potent vaccine was effective, but 3 weekly doses induced a greater degree of resistance (see *Public Health Reports*, 1947), within recent years, on the basis of this work, several American organizations have recommended the annual prophylactic vaccination of dogs as an effective means of controlling canine rabies.

D. ANTIRABIES TREATMENT OF EXPERIMENTAL ANIMALS AFTER INOCULATION WITH LIVING VIRUS

The most obvious method of assessing the efficiency of antirabies vaccines for use in the treatment of human beings is to test their effect in preventing rabies when administered to animals after experimental infection This method simulates as closely as possible what happens when vaccines are used in practice. A number of experiments has been carried out in the past, and the question has been critically reviewed by Webster (1939 *a*, 1942) whose papers have attracted the widest interest Numerous workers have obtained negative or virtually negative results. Thus, following intracranial injection of street or fixed virus in rabbits, dogs, and rats, courses of attenuated, diluted, and phenolized vaccines have failed to prevent the onset of rabic symptoms in a significant proportion of animals (von Frisch, 1887, Hoegyes, 1889 *a*, *b*, Fermi, 1908).

Workers in India infected rabbits and monkeys by corneal scarification, and treated them with phenolized, etherized, and phenol-ether vaccines The rabbits were not protected from rabies, about 60 per cent of vaccinated monkeys died, as compared with 72 per cent. of controls (Cunningham and Malone, 1930, Cunningham *et al.*, 1933) This work in India was continued with monkeys, and in a series of experiments well over 1000 animals were used Infection was usually secured by injecting street virus intramuscularly in the neck, phenolized vaccines with and without antirabic serum being administered subsequent to infection Although some protection was achieved, the results were most disappointing, as it was not possible to protect as many as 50 per cent. of animals It should be remembered that in experiments of this kind, approximately one quarter of the control animals fail to develop rabies, as street virus does not infect regularly by the intramuscular route (Shortt *et al*, 1934, 1934–5, Covell *et al*, 1936–7)

Other workers have carried out similar experiments, and although some vaccines may have appeared to protect, the numbers of animals used have been too small to draw conclusions (Remlinger, 1919 *c*, Lépine and Sautter, 1937)

Schweinburg (1930) claimed that this was so, but Remlinger has disagreed (Remlinger *et al.*, 1931 *b*, Remlinger and Bailly, 1931 *a*).

Histological reaction in vaccinated animals. Immunization by the desiccated cord method was found to produce definite lesions in the central nervous system (Nicolau, Cruveilhier, and Kopciowska, 1931 *a*, *b*, Cruveilhier, Nicolau, and Kopciowska, 1935). These reactions have been attributed to a mild infection, the virus is only attenuated and probably the reaction is one of defence. Some cellular infiltration may be found in the meninges In the cerebral cortex there are areas of mononuclear infiltration and microglial reaction. Very marked satellitosis of nerve cells occurs in the mesencephalon and diencephalon. In the cord, the posterior horn is infiltrated with mononuclear cells, satellitosis may be seen. The Nissl bodies may be degerate and agglomerated in large masses. In the spinal ganglia a parenchymatous infiltration of mononuclears and a proliferation of capsular cells are usually present. Lépine and Sautter (1938) have reported that nuclear inclusions (see p. 831) develop in the brain after injection of phenolized virus, this they attribute to the presence of living virus in their vaccine.

The reticulo-endothelial system in acquired immunity. Immunity can be acquired by splenectomized dogs (Plantureux, 1932). A previously acquired immunity can, however, be abolished by blockade with India ink (Loeffler and Schweinburg, 1933–4). Further, Loeffler and Schweinburg (1932 *a*) have shown that the serum of animals blockaded with India ink and vaccinated is less virucidal than that of unblockaded animals, in addition, these animals are less protected against reinfection than unblockaded animals. The reticulo-endothelial system would seem, therefore, to play a definite rôle in resistance to infection.

C. PROPHYLACTIC ANTIRABIES TREATMENT OF ANIMALS

In various parts of the world where rabies is endemic, prophylactic immunization of dogs and sometimes other animals has been carried out, in an attempt to limit the spread of the disease (Remlinger, 1919 *a*, Plantureux, 1926 *a*, Vallée, 1927, Remlinger and Bailly, 1932 *a*, 1934 *c*; Balozet, 1938 *a*, *b*, Gautier, 1940) The following vaccines have been used

(*a*) Living *virus fixe* vaccines (Roux and Nocard, 1888, Galtier, 1897, Schnurer, 1905, Remlinger, 1921, Jonesco, 1930 *b*)
(*b*) Hoegyes' vaccine (Aujzesky, 1922)
(*c*) Desiccated cords (Babès and Bobes, 1912)
(*d*) Finzi's vaccine (Vallée, 1927)
(*e*) Marie's vaccine (Rodet and Galavielle, 1900, Marie, 1905 *c*, Remlinger, 1905 *g*, 1909 *b*, Shortt *et al*, 1934–5)
(*f*) Miessner's (1912) vaccine
(*g*) Oil-emulsion vaccines (Botofogo Gonsalves, 1924, 1926 *a*, *b*)

More use has, however, been made of the following methods

(*h*) Etherized vaccines (Remlinger, 1918 *a*, 1919 *a*, 1925 *c*, Bailly, 1926, Remlinger and Bailly, 1930 *f*, 1932 *a*)
(*i*) Chloroformized vaccines (Kelser, 1930, Schoening, 1930, Barnes *et al*, 1934, Webster, 1939 *b*, 1940, Leach and Johnson, 1940 *c*, Webster and Casals, 1942 *a*)
(*j*) Formolized vaccines (Konieff and Ramsine, 1928, Plantureux, 1935, 1938)
(*k*) Phenolized vaccines, attenuated or killed (Umeno and Doi, 1921, Kondo, 1922, Kitt, 1925, Velu *et al*, 1926, 1928, Plantureux, 1926 *a*, *d*, Legezynski and Markowski, 1928 *a*, Markowski and Legezynski, 1928 *a*, Dos Santos, 1929, Schoening, *1925, 1928, 1930, 1931*)
(*l*) Irradiated vaccines are highly effective immunizing agents (see p. 845), Webster and Casals, 1942 *a*)

Vaccines are usually given in one dose subcutaneously or preferably intraperitoneally. It is very questionable how much resistance has been induced by many of

Cruveilhier *et al*, 1938, DaCosta, 1938, Moss, 1939–40, Kligler and Bernkopf, 1941 *a*, Bronshten and Zak, 1942, Friedemann, 1947; Friedemann *et al*, 1944, and others)

Virus strains vary considerably in their capacity to stimulate the production of antibodies, some scarcely doing so at all (Remlinger and Bailly, 1931 *b*). It has been noted that there is little correlation between the antirabic titer of the serum and the quantity of inoculum, and that the titer may fluctuate, especially in sheep (see Remlinger, 1907 *d*, Marie, 1927 *b*). A strongly antirabic sheep serum in a quantity of 1 c c. may neutralize 40 times its bulk of 1 per cent. virus suspension (see Marie, 1907 *a*). Habel (1940 *b*) produced a hyperimmune rabbit serum by repeated doses of phenolized vaccine followed by inoculation of live virus Later, he found that intracutaneous inoculation of live virus was more effective (1945) The rabicidal properties may persist for a considerable time after inoculation (Webster, 1936)

Nature of the rabicidal antibody. A number of authors has investigated the nature of the rabicidal antibody, and the rabies antigen-antibody reaction (Marie, 1905 *a*, 1908, 1912 *a*, Kondo, 1922; Nikolajewa, 1925, Lubinski and Prausnitz, 1926, Isabolinski and Zeitlina, 1929, Shortt *et al.*, 1934–5). There is some difference of opinion with regard to the nature of the reaction between antigen and antibody, some saying it occurs in multiple propertions, some saying the union is stable, and others saying it is easily broken down Kondo states that the optimum time and temperature for union between antigen and antibody is 2 hours at 37° C., or 20 hours at 18° C to 20° C (in the dark). Friedemann *et al* (1944) found that virus and antibody combined *in vitro* even if the immune serum was highly diluted The properties of the rabicidal antibody are as follows It is destroyed by 80° C. for half an hour, but there is no change at temperatures below 70° C applied for half an hour It is associated with the globulin fraction (Shortt *et al*) Immune body can be absorbed by virus.

Antirabic properties of immune tissues Kubes and Gallia (1944) have claimed that the brain tissues of mice immunized with antirabies vaccines contain substances neutralizing the virus *in vitro*, and the more the animal has been immunized the greater this neutralizing effect They state that the results of the tissue neutralization test agree with those obtained by protection experiments

Virus was found to disappear from the site of injection more rapidly in immunized mice and guinea-pigs than in controls, and failed to invade the nervous system (Habel, 1941 *b*, Kligler and Bernkopf, 1943)

The significance of the rabicidal immune body As Stuart and Krikorian (1932 *a*) emphasized, there is divergence of opinion as to whether rabicidal substances indicate resistance to infection or not They could not detect any mathematical relationship between rabicidal content of the serum and the degree of resistance to infection Jonnesco (1932 *b*) also failed to elicit any parallelism between rabicidal power of the serum and resistance to reinfection (see also Habel, 1941 *b*, Kubes and Gallia, 1944) Further, as Remlinger and Bailly (1928 *a*) point out, in the human being rabicidal powers do not necessarily develop after vaccination, although the patient appears to be protected against rabies Moreover, fatal cases of rabies have been known to have a highly rabicidal serum In vaccinated mice, although immune bodies and resistance usually develop together, there may be lack of correlation (Webster, 1936, Casals, 1940 *b*) Fowls may be rendered resistant to virus yet show no antibodies (Kraus and Maresch, 1902) On the other hand, it has been said that in rabbits, those showing rabicidal properties are always immune to reinfection (Cruveilhier and Viala, 1937)

F. PASSIVE IMMUNITY

A number of workers has tested the effect of antirabic serum on experimental rabies Thus, they have been able to prevent the development of rabies in experimental animals by injections of serum made just before or just after that of the virus (e g, Babès and Lepp, 1889, Babès and Talasescu, 1894, Kondo, 1922, Pono-

Fermi (1908) obtained more satisfactory results by infecting rats subcutaneously with *virus fixe*, and treating with phenolized vaccines. Large doses of vaccine were, however, needed (over 20 c.c. per rat) to protect the infected animals (see also Mulas, 1936, who worked with rabbits).

Habel (1940 *a*), working with guinea-pigs injected intramuscularly with street virus, was able to protect 16/27 by a series of 21 daily injections of 0.5 c.c. phenolized vaccine; 4/5 controls developed rabies.

In another series of experiments, mice infected intramuscularly with street virus were not protected by subsequent injections of phenolized virus, although chloroformized vaccines occasionally protected, when, however, 5 doses of an irradiated vaccine were given, rabies was prevented in most cases (Webster, 1939 *b*, Webster and Casals, 1942 *a*). Habel (1947), using irradiated virus, demonstrated some protection against death from street virus in guinea-pigs immunized after infection.

We may conclude, therefore, that it is difficult to protect animals by antirabies treatment given subsequently to infection. Large doses of phenolized, chloroformized, and potent irradiated vaccines may, however, secure protection in the smaller laboratory animals.

E. ANTIBODY PHENOMENA IN EXPERIMENTAL RABIES

The precipitating antibody. According to a majority of authors, precipitating antibodies do not develop (Burmeister, 1915, Kondon, 1922; Lässer, 1927, Schultz, Bullock, and Brewer, 1928). Of more recent years, however, Havens and Mayfield (1932 *a*, *b*, 1933) have claimed that flocculation occurs between rabies virus and antiserum. Further, they find that antigen can absorb its specific immune body. They have used this method for investigating the antigenic structure of rabies virus.

The complement fixing antibody. Rabbit, horse, or other animal immune serum may fix complement with salivary gland extract from rabid animals or human beings (Nedrigailoff and Sawtschenko, 1910, Zell, 1913). Animal brain antigen may also be used (Marie and Urbain, 1929, Greval, 1932–3). Using a cocto-antigen, Kraus and Takaki (1926) obtained positive fixation with rabbit immune serum Kraus and Michalka (1926) substituted a glycerolited antigen instead of the cocto-antigen, and rendered the reaction more specific Shortt *et al* (1934–5) were also able to elicit a positive fixation reaction, and suggested that the method could be used to standardize antirabic serum Kostrezewski (1920) obtained a positive reaction with the sera of treated patients, using a cord antigen

Recently Casals has popularized the use of the CFT (Casals, 1942, 1947, Casals and Palacios, 1941 *a*, *b*) Antigen can be prepared from brain rendered noninfective by freezing and thawing or ultraviolet light, complement fixing antibodies develop to high titer in rabbits, mice, guinea-pigs, and dogs immunized with virus Antigen prepared by desiccating brain over sulfuric acid, and suspending in saline, can be used (Bernkopf and Nachtigal, 1943, Nachtigal, 1945). Nachtigal (1945) has claimed that the complement fixing antigen is "soluble" and occurs in the supernatant of centrifuged suspensions of infected brain

Despite these results, the occurrence of complement fixation in rabies has been denied (Baroni, Cinca, and Ionescu-Mihaiesti, 1908, Schultz, Bullock, and Brewer, 1928, Stuart and Krikorian, 1929–30)

Monkeys developing rabic infection were found to show no complement fixing antibodies although the virus neutralizing titer was high (Habel, 1945) Nachtigal (1945) also found a lack of correlation between the two antibodies, *in guinea-pigs*

The rabicidal antibody Many authors have demonstrated the development of rabicidal properties in the serum of animals treated by live or killed vaccines or tissue cultures, by the usual type of virus neutralization test (see, e g, Babès, 1891, Kraus, Kellner, and Clairmont, 1902; Schnurer, 1905, Marie, 1905 *a*, 1908; Semple, 1908, Kondo, 1922, Stuart and Krikorian, 1925, 1929–30, 1932 *a*, Jonnesco, 1939 *b*,

munized with normal central nervous tissue. Similarly, injections of normal rabbit brain did not produce rabicidal antibodies (Remlinger, 1909 *b*, Kondo, 1922). Harvey and Acton (1922–3) immunized 2 sheep, one with *virus fixe* and the other with normal rabbit brain. Although some antirabic properties developed after inoculation of normal brain, these were not so powerful as those produced by injection of *virus fixe*. Stuart and Krikorian (1929–30) were unable to stimulate the development of rabicidal antibodies in rabbits treated with normal nervous tissue

Thus far the specificity of the response appears to be proved However, the specificity of rabicidal serum has been questioned by Babès and Simici. They found (1910 *a*) that mice could be passively immunized (after infection) with the serum of a dog that had been injected with normal nervous tissue Further (1910 *b*), they stated that mice could be immunized by injections of normal central nervous tissue (Repetto, 1908, made similar observations) Despite these adverse observations, it is generally accepted that the rabicidal antibody is produced as a specific response to the injection of the virus of rabies *per se*.

H. THE NATURE OF ANTIRABIC IMMUNITY

From what has been said above, it will be evident that animals can be fairly readily immunized by injections of live or killed virus so as to withstand even an intracerebral test dose. Although the acquisition of this immune state may be accompanied by the development of serum antibodies, this is not invariable It would appear that virus fairly rapidly disappears from the site of inoculation in immune animals, probably due to an antiviral property of the tissues, and does not invade the nervous system. It seems reasonable to suggest that both humoral and tissue neutralizing substances are concerned in the destruction of virus introduced into the immunized animal

It is not nearly so easy to prevent the development of rabies if treatment is delayed until after the infection has been initiated. A beneficial effect can, however, be achieved by potent vaccines, vaccines plus serum, or serum alone. Serum presumably acts by a direct neutralizing effect on the virus before it invades the nerves Vaccination must in some way immunize the nervous tissues, so that the infecting virus fails to progress, but the precise mechanism is obscure. It may be that vaccines in some way occupy the susceptible cells before the arrival of the infecting virus, thus causing an "interference" phenomenon.

mareff and Solovieff, 1928). Hoyt and his coworkers have reported that antirabic (*rabbit*) *serum can protect mice when it is injected before an intracerebral test* dose of virus (Hoyt *et al*, 1936, Hoyt and Gurley, 1937–8, 1938). Further, they showed that injections of serum given after the test dose, even up to 4 days, still protected. A similar preventive effect of antirabic serum was observed if mice were *injected in the tail* (Proca, Bobes, and Jonnesco, 1935), or intramuscularly (Yen, 1942).

After inoculation of the pad in guinea-pigs, injections of sheep antirabic serum were shown to have a definite preventive effect (Proca, Bobes, and Jonnesco, 1934 *a*, *c*).

It has been found that intraspinal injections of serum, given just before or just after inoculation of virus, protect dogs and rabbits (Speransky, 1927; Ponomareff and Tchechkoff, 1927). The intraspinal injection was given after withdrawing *cerebrospinal fluid. If lumbar puncture was first carried out, intravenous injection* also protected these animals It is probable that this technique acted by altering the blood-brain barrier so as to allow the antibody to reach the nerve tissue. Intravenous injections of thionin have been found to have a similar effect on the blood-*brain barrier, and after such administration, antirabic serum injections may have a* powerful prophylactic effect (Loeffler and Schweinburg, 1932 *b*). Friedemann *et al.* (1944) injected virus intraventricularly in guinea-pigs, and administered serum intravenously, and found that there was a definite protective effect with adequate doses of serum.

Important experiments were carried out by Habel (1945) in guinea-pigs and mice Serum treatment of infected animals gave consistently better results than vaccination alone. Serum was most effective given intramuscularly at the site of inoculation. The protection was more effective if the serum was given immediately after the inoculation of virus. After infection with street virus, the most effective means of preventing rabies was to give serum up to 3 days later, and begin vaccine treatment 6 days after the administration of serum.

G. THE SPECIFICITY OF RABIC IMMUNITY

1 *The specificity of resistance to infection* It is generally held that the resistance of animals to infection after injection of *virus fixe* is a specific response to the virus Certain workers, however, have claimed that normal nervous tissue is capable of conferring antirabic immunity Thus Babès (1892, 1898) claimed that normal sheep's brain rendered dogs resistant to injections of street or fixed virus Fermi (1909 *b*) also advanced the antigenic potency of normal nerve tissue.

Against these observations, Remlinger (1909 *a*) was unable to immunize rabbits with normal homologous brain Harvey and Acton (1922–3) failed to protect dogs, monkeys, or guinea-pigs against virus by treatment with normal cord (prepared as in Pasteur's or Hoegyes's method) or normal brain (carbolized). Stuart and Krikorian (1929–30) were unable to confer any antirabic immunity on animals with carbolized normal brain.

2 *The specificity of the rabicidal antibody* First, the normal serum of cattle, horses, sheep, dogs, rabbits, guinea-pigs, and fowls is not rabicidal (Kraus, Kellner, and Clairmont, 1902, Kondo, 1922).

Secondly, as Harvey and Acton (1922–3) pointed out, the development of antirabic properties after injection of *virus fixe* might, theoretically, be due to the following causes

(*a*) A specific antibody response to the rabies antigen

(*b*) An antibody response to a nonspecific toxic constituent of the brain infected with fixed virus

(*c*) The production of a neurolysin in response to the injected brain

Various attempts have been made to exclude the 2nd and 3rd possibilities. Marie (1904 *b*) found that rabicidal properties did not develop when sheep were im-

ized vaccines It might, therefore, seem as if these vaccines should rapidly have supplanted live vaccine. No such result was, however, achieved, largely owing to the belief of the French that inactivated vaccines were inferior immunizing agents to living preparations At the Rabies Conference in 1927, for example, Calmette declared the superiority of living vaccines, there the position might have remained, but for the publication of numerous detailed statistical analyses by McKendrick This worker has shown that there is no difference in the immunizing capabilities of living or dead vaccines, when given in approximate dosage. These statistical reviews

linger and Bailly, 1939 *a*, Lépine, 1946).

INDICATIONS FOR ANTIRABIES THERAPY

Antirabies treatment should be started immediately when a person is bitten or scratched under the following conditions (Johnson, 1943) (1) The animal presents clinical signs of rabies (2) The animal is proved positive for rabies by laboratory

1940)

The amount of treatment is dependent on the degree of risk, and this is conveniently assessed by reference to Hempt's, or the newer Indian classification given on p 870

TISSUE USED IN ANTIRABIES VACCINES

Vaccine is usually prepared from rabbit brain or cord infected with *virus fixe* Sheep brain vaccine (5 per cent carbolized) is used in India and elsewhere, and has a higher antigenic value than sheep cord vaccine (Shortt *et al*, 1934, Covell *et al*, 1936–7, Dunlap, 1943) Monkey brain has also been used for treatment, e g, by the Hoegyes method (van Stockum, 1935, 1941) It has been found that removal of brain tissue from the vaccine lowers its immunizing value (Taylor and Menon, 1930). It may eventually prove possible to produce a vaccine for human use from tissue cultures

Golovine (1941) made the suggestion that if no vaccine could be obtained one could be prepared from the brain of the biting animal in an emergency

PROPERTIES OF *VIRUS FIXE* IN ANTIRABIES VACCINES

Choice of *Virus Fixe*

It is generally agreed that the classical Paris strain of *virus fixe* is the best immunizing agent It has been shown experimentally (Cunningham, Malone, and Craighead, 1933, Shortt *et al*, 1937), and in man (Shortt *et al*, 1934), that the Paris strain is a better immunizing agent than Kasauli and other Indian strains of *virus fixe*

strains passed more frequently were more highly antigenic The number of passages removed from the original Pasteur strain had no relationship to immunizing ability, yet of 5 strains fixed more recently, 3 gave a very high degree of protection Hampil and Roberts (1942), in similar studies in mice, found that substrains of the same

CHAPTER LXXVIII

HUMAN ANTIRABIES TREATMENT

HISTORICAL

In 1884 Pasteur, Chamberland, and Roux[1] reported that they had been able to immunize some 23 dogs experimentally against rabic infection. By the following year a method had been evolved which was capable of being applied to human beings. Thus, Pasteur (1885) reported that the cords of rabbits infected with *virus fixe* could be so treated that the virus became of greatly reduced virulence. Briefly, cords were suspended in dry air over potash, and the longer they were left to desiccate the less virulent they became.

On July 6, 1885, Joseph Meister, aged 9 years, arrived in Paris (see Pasteur, 1885). He had been badly bitten by a rabid dog on July 4, numerous wounds were situated on the hand, arm, and thigh. Although the wounds had been cauterized, Pasteur held that the child was doomed to die, and he injected the boy that day with a cord that had been desiccated for 14 days, the injection was given subcutaneously in the abdomen. The treatment was continued as follows: 2nd day, 14-day cord and 12-day cord, 3rd day, 11-day cord and 9-day cord, 4th day, 8-day cord, 5th day, 7-day cord, 6th day, 6-day cord, 7th day, 5-day cord, 8th day, 4-day cord, 9th day, 3-day cord, 10th day, 2-day cord, and finally on the 11th day, Joseph was injected with a fully virulent 1-day cord. Joseph remained in perfect health, and grew up to become the *concierge* of the Pasteur Institute.

The 2nd case was treated on October 20, 1885, the patient having been bitten 6 days previously, no rabies developed. By the 25th of February, 1886, Pasteur reported (1886 *a*) that he had administered his 350th prophylactic treatment, by the 12th of April, 726 had been treated (Pasteur, 1886 *b*). Of 688 cases treated after a dog bite only 1 died, whereas 3 of 38 persons bitten by a wolf were not saved by the treatment. By the 31st of October 1886, no less than 2,490 persons had undergone a course of prophylaxis. The treatment lasted for 6 days, beginning with a 14-day and ending with a 5-day cord. In this series there were 12 deaths (Pasteur, 1886 *c*). The actual plan of injections was modified somewhat with the passage of time (*vide infra*).

The treatment aroused the greatest possible interest in medical circles. Although some antagonistic communications appeared (see, e g, Dolan, 1886, Spitza, 1886), the general opinion was most favorable. In 1887 a number of medical men in Britain prepared a report and expressed themselves satisfied (*Rep loc Govt Bd*, 1887).

The 50th anniversary of the introduction of the treatment was suitably commemorated in Paris in 1935. A special supplement to the *Annales de l'Institut Pasteur* for 1935 was published, containing papers on antirabies treatment by Vallery-Radot (1935) and Lépine and Cruveilhier (1935 *a*), as well as many other articles on rabies.

Pasteur's original method has always been the method of choice in France and her colonies, in other parts of the world, however, numerous modifications have been introduced. Thus Hoegyes, in 1887, reduced the virulence of *virus fixe* by dilution. Both these vaccines contained, of course, living virus. From 1907 to 1911 phenolized vaccines were introduced by Fermi, and later modified by Semple. These vaccines contain inactivated virus—a radical difference from the earlier vaccines.

Although usually harmless, antirabies treatment has occasionally, from the earliest days, been followed by severe and sometimes fatal accidents. It was soon found that the incidence of such reactions was very considerably reduced by the use of phenol-

treatment, e.g, by the

Hoegyes method (van Stockum, 1935, 1941) It has been found that removal of brain tissue from the vaccine lowers its immunizing value (Taylor and Menon, 1930). It may eventually prove possible to produce a vaccine for human use from tissue cultures.

Golovine (1941) made the suggestion that if no vaccine could be obtained one could be prepared from the brain of the biting animal in an emergency.

PROPERTIES OF *VIRUS FIXE* IN ANTIRABIES VACCINES

Choice of *Virus Fixe*

It is generally agreed that the classical Paris strain of *virus fixe* is the best immunizing agent It has been shown experimentally (Cunningham, Malone, and Craighead, 1933, Shortt *et al*, 1937), and in man (Shortt *et al*, 1934), that the Paris strain is a better immunizing agent than Kasauli and other Indian strains of *virus fixe* Habel (1940 *b*) studied 31 strains, 25 being derived from Pasteur's original He found a wide range in immunizing ability in mice in these strains. Apparently a high immunizing potency against a heterologous test virus is not an inherent characteristic of a

ties

sista

strai

rem

vet

and Roberts (1942), in similar studies in mice, found that substrains of the same

strain might vary considerably, and be weakly antigenic even against a test injection of homologous virus.

From what has been said it will be evident that the properties of *virus fixe* should be carefully checked from time to time (see below).

Alterations in the Properties of *Virus Fixe*

Many strains have been passaged since about 1886, and it is natural to inquire whether they have undergone any change that might affect their use in antirabies treatment. This question has been studied particularly by Remlinger, and is summarized in a review (1935 *a*), and also in papers with Bailly (1935 *a, b, c*), and by Habel (1940 *b*).

(*a*) *Virulence of fresh* virus fixe. Certain changes have been recorded in the length of the incubation period in animals. Thus, examining the Lille strain in 1930, Grysez and Marneffe (1935) found that the 6-day incubation period of earlier days had become replaced quite frequently by a 5-day period. Habel (1940 *b*) found that the period varied from 4–13 days with different strains.

Discussion has taken place whether fresh *virus fixe* has lost its pathogenicity to certain animals, but, using the intra-ocular route in rabbits, Marie (1923, 1927 *a*) found the Paris strain as virulent as previous. Contrary results have, however, been obtained by others Thus, Puntoni (1922) reported that the strain of *virus fixe* in Rome had become nonpathogenic on intraocular injection; Plantureux (1928) reported that the Algiers strain was losing virulence by this route, although 2 years previously it had been active (1926 *a*). The Tangier strain was found to be inactive by intraocular injection (Remlinger and Bailly, 1927 *c*)

Habel (1940 *b*) found all but one of his strains to be infective for mice by the intramuscular route. We ourselves have studied the properties of a British strain of *virus fixe* passed in guinea-pigs for many years. This strain usually infects by the intramuscular route only at a dilution of 10^{-1}. Tested by the intraocular route it behaves irregularly and occasionally infects at 10^{-3}.

(*b*) [illegible] passage, certain strains r[illegible] 13) noted that there w[illegible] changed over to a newly fixed virus, and this resulted in a lowering of the mortality. However. [illegible]

[illegible] 1940 *b*).

(*c*) *Resistance to desiccation* In 1923 Remlinger (1923 *c*) stated that the Tangier strain (2,200th passage) was more susceptible to desiccation than formerly Thus, while 3-day cords were always virulent, 4-day cords were only virulent in 50 per cent of cases, and 5- and 6-day cords were avirulent. Somewhat similar results were reported by Bablet (1925) from Saigon By 1934 Remlinger found (see 1935 *a*) that 3-day cords were sometimes avirulent, and even on occasions 2-day cords In the early days of this strain 5- and 6-day cords had proved virulent, so a considerable increase in susceptibility had occurred. Similar results were reported from Paris, where even 1-day cords were sometimes avirulent (Lépine, Cruveilhier, and Sautter, 1935, Lépine and Cruveilhier, 1935 *a*)

Various other institutes have reported a simil[illegible] cation, although not all strains show this featu[illegible] Thus, the Lyons strain in 1927 was still viruler[illegible] Bertoni (1938) reported that 5-day cords were still virulent at Boulogne, Virga [illegible] days' desiccation. Marie (1926) drew [illegible]sed as the test animals instead of rab- [illegible] Institute might prove virulent The

route of injection is also of importance in determining the possible avirulence of a ... was viru- ...) similarly ... n injected intraocularly and by other routes The most sensitive method of testing for live virus is the intracerberal injection of mice (see below).

(d) *Infectivity on d* ... *virus fixe.* Thus, in 188 ... lent, but later Remlinge ... *fixe* was active. Habel ... hundred-fold when tested in mice, ranging from 10^{-3} to 10^{-5}.

(e) *Resistance to glycerol* When this method was introduced by Calmette (1891) virulence was retained for about 1 month, even if cords had been previously desiccated for a few days The effect of passage on the Tangier strain was to render it more susceptible to glycerol, so that 2- to 3-day desiccated cords lost virulence after only 7 to 8 days' immersion (Remlinger, 1923 *d*, 1935 *a*) Rochaix (1923) reported a similar loss of resistance in the Lyons strain of *virus fixe*, and Grysez (1937) in that of Lille Not all strains of virus, however, have shown this increased susceptibility. For instance, 2-day cords infected with the Tunis *virus fixe* retain virulence in glycerol for up to 9 weeks (Burnet, 1925).

It must be remembered that the temperature of storage plays an important rôle in the duration of infectivity, virulence being retained best at low temperature. To quote an actual example, it was found that 1-, 2-, and 3-day cords remained virulent for at least 20 days at a temperature not over 10° C When, however, the temperature was raised to 20° C. virulence only lasted for less than 10 days (Girard and Robic, 1927)

(f) *Resistance to ether* With continued passage various *virus fixe* strains have been found to develop an increased susceptibility to ether. Thus Remlinger, Palmowitch, and Bailly (1931 *c*) studied the following strains of *virus fixe*, namely virus Z, Chisinau, and virus of *mal de caderas;* they were all rendered avirulent after 120 hours, whereas previously destruction had taken 144 hours. They reported a similar increased susceptibility for another virus strain (B).

However, the results of ether resistance tests must be regarded as somewhat variable In 1934–5 Remlinger (see 1935 *a*) repeated his original (1919) work on the resistance of Tangier *virus fixe* infected brains to ether, he found that such brains now resisted treatment for 250 to 280 hours, although previously 120 to 125 hours had sufficed for destruction.

In conclusion, therefore, the effect of continued passage on *virus fixe* has been to increase its susceptibility to desiccation and glycerol, but to render it more resistant, certainly to dilution and in some cases to ether as well

Preservation of Virulent Fixed Virus

1. The first method introduced to meet this need was glycerol (Roux, 1887, Calmette, 1891, Rodet and Galavielle, 1901 *a*, 1902, Nicolle, 1904) Habel (1940 *b*) found that 4 strains lost their infectivity after 3 months in 50 per cent glycerol at 0° C., 4 were viable up to 6 months, and 23 for 6 months or longer. When brain tissue is immersed in glycerol, infectivity is lost from the periphery inwards, and therefore the larger the piece of tissue the longer it remains virulent (see Remlinger, 1924 *a*). Further, the higher the temperature at which storage occurs, the quicker is virulence lost (Protopopoff, 1889)

... not ... loc ... undesirable ingredients of a human vaccine these organisms may eventually cause the virus to die out (Remlinger, 1923 *b*)

2. A better method is cold storage, as virus retains its virulence in the cold (+4° C. to −10° C.) for a long time, especially when frozen (Viala, 1891; Puntoni, 1924; Stuart and Krikorian, 1929–30, Remlinger and Bailly, 1934 *b*, Lépine, 1935). Under these conditions virus *may retain its virulence for a year or longer. Storage* in a carbon dioxide ice box is the method of choice.

3. Virus rapidly desiccated preserves its virulence for some months (Vansteenberghe, 1903, Baroni, 1927).

4. Although virus maintains its virulence in olive oil for some weeks (Botafogo Gonsalves, 1924), this treatment renders the brain soft, disintegrated, and scarcely suitable for use in antirabies treatment (Remlinger, 1924 *c*)

5. Formol serum, phenol serum, and formol glycerol serum have been said to preserve virulence for about 3 weeks (Plantureux, 1925 *a*, *b*), Remlinger and Bailly (1925) regard the method as inferior to glycerol for antirabies vaccines

Maintenance of Titer of Fixed Virus

With any one strain of fixed virus the greater the amount of virus material the greater the immunizing capacity of the vaccine. It is, therefore, desirable to insure the maximal titer in the brain used as source of inoculum. Habel (1941 *a*) recommends that rabbits be inoculated intracerebrally with 0.2–0 25 c.c. of a 1/1000 dilution of supernatant fluid from the suspension of a previously passed brain The animal should be killed after it has been completely paralyzed for at least one and preferably two days After killing by chloroform, or exsanguination, the brain may be kept for a short time in glycerol or at −10° C. The cord should be discarded. Frequency of passage does not influence the final titer in the paralyzed animal (see also Remlinger and Bailly, 1935 *a*).

Periodical Checking of Properties of *Virus Fixe*

Laboratories preparing antirabies vaccines should periodically test the properties of their strain, along the following lines recommended by Habel (1940 *b*) The specificity of the virus should be checked by neutralization tests with known rabies antiserum Samples of virus should be removed at intervals during the process of treatment with chemicals and tested for virulence in mice. Rabbit brains should be examined for virus content by titration in mice Mice should be immunized with the final vaccine, and challenged with a known rabies virus When live vaccines are being used, in addition, the infectivity for mice by the subcutaneous route should be estimated. Also, in the Pasteur method, samples of cord desiccated for varying periods should be tested by mouse inoculation for virulence.

TESTING OF VACCINES FOR VIRULENCE

Chemically prepared vaccine must be tested by animal inoculation. Advantage should be taken of the susceptibility of the mouse, and at least 5 2-week-old mice injected intracerebrally with 0 03 c.c. of a 1:10 dilution of the vaccine (Webster, 1939 *b*)

ROUTE OF INJECTION

The vaccine is usually injected subcutaneously, often in the abdomen The intravenous route has been recommended (Téodorasco, 1923 *a*, *b*; Morison, 1924) but is seldom used Intradermal injection is also practiced

A. VACCINES IN COMMON USE

In the following pages we shall discuss those methods which feature in Greenwood's (1945–6) statistical review of antirabies treatments, that is to say, those methods which are being used to a greater or less extent by various antirabies institutes throughout the world These methods are as follows [1]

[1] The numbers used in referring to these vaccines are those employed by Greenwood (1945–6)

1. Desiccated cord method and modifications (Pasteur and Calmette)
2 Hoegyes's dilution method
3–6 Phenol methods–modifications of Fermi's method, viz
   3. Killed phenol methods (Semple and Mulford)
   4 Live phenol (Puntoni's) method
   5. Fermi's original method
   6. Fermi's serovaccine
7 Heated nerve tissue methods (Babès)
8 Killed ether (Hempt's) method
9. Mixed methods
   (a) dilutions plus, in severe cases, Alivisatos's ether method
   (b) dried cords plus, in severe cases, Fermi's original method (5)
   (c) Fermi's vaccine plus, in severe cases, Alivisatos's

These vaccines may also be grouped under four headings as follows
(a) Killed vaccines (3 and 8)
(b) Live vaccines (1, 2, 4, 9 a, b)
(c) Heated vaccines (7)
(d) Other vaccines (5, 6, 9 c, 10)

1. Desiccated Cord Method

The effect of desiccation on fixed virus It was realized from the start that virulence was usually lost in cords after about 5 to 6 days of desiccation over potash, 5- and 6-day cords usually being noninfective, while 4-day cords were virulent (see, e g, Gamaleia, 1887 *d*, Rodet and Galavielle, 1901 *b*). The curve of infectivity of cords subjected to desiccation falls rapidly during the first 3 days, and very slowly thereafter to the 9th day, the loss of infectivity was found to be directly proportional to the rate at which the contained moisture is lost (Harvey and McKendrick, 1907)

The exact loss of virulence that occurs with desiccation is greatly affected by the temperature Thus, other things being equal, cords desiccated at the usual 23° C lose virulence quicker than cords treated at 4° C. There seems to be considerable variation between different institutes with regard to the temperature used for desiccation, and Remlinger (1925 *d*) has entered a plea for greater uniformity.

The fact that with continued passage certain strains of *virus fixe* are now very much more susceptible to desiccation than formerly has already been mentioned In fact, Lépine (1938) has stated that it may become necessary to give up cord altogether.

Preparation of vaccine This method of antirabies treatment was, of course, originated at the Pasteur Institute in Paris, and is most widely used in France and her colonies We shall describe the method with particular reference to the present-day technique detailed by Lépine and Cruveilhier (1935 *a*) Reference will also be made to the practical information furnished by Harvey and Acton of the Kasauli Institute (1922–3) The strain of virus used in Paris for the preparation of vaccine is the original classical strain, it has been passaged continuously since the days of Pasteur Rabbits are most commonly used as experimental animals and are injected subdurally with *virus fixe* If dogs are being used for injection, the intracerebral route is preferable to the subdural In carrying out the subdural inoculation, the usual practice is to inject virus under the dura, from behind forwards, through a small trephine opening in the angle of the coronal and sagittal sutures but, if desired, the skull may be perforated with a sterile nail or drawing-pin (Remlinger, 1926 *a*)
To preve
(a) slow
with a sv
withdrawn slowly Care should be taken that antiseptics do not enter the needle hole

At the present day rabbits are killed when paralysis sets in (6th to 7th day), instead of, as formerly, waiting until they die. It was often found that the cord removed in such circumstances was contaminated with organisms (see, e g, Kuhne, 1921, Remlinger, 1923 *a*, Isabolinsky, 1924). Cords are best removed by cutting the vertebral column across high up and low down, and pushing the cord out (from below upwards) with a sterile nickel rod. The cords should be received into sterile receptacles, and routine cultures made. Each cord is cut into 2 or 3 pieces and suspended by a sterile wire in tubes in a special flask with caustic potash at the bottom. The flasks are then incubated at 23° C. When the desire length of time has expired, the cords are placed in glycerol and stored on ice.

Human inoculation. A typical course of injections with desiccated cord, as used at the present day, is shown in Table 33. Each dose consists of about 3 to 4 mm of cord emulsified in 3 c.c. of sterile water.

TABLE 33 [1]

SPECIMEN PRESENT-DAY COURSE OF ANTI-RABIES TREATMENT WITH DESICCATED CORDS

[1] Modified from Lépine and Cruveilhier (1935 *a*) in accordance with a personal communication from Dr Lépine (July 1946).

Cases least at risk are treated for 15 days, average cases for 18 days, more serious cases for 21 days, and the most serious cases for 25 days.

Modifications of the desiccated cord method.

(*a*) *Glycerol modification.* Antirabies treatment can be carried out with cords which have remained in glycerol for decreasing periods of time, without being desiccated at all Thus, the first injections consist of cord which has been in glycerol for about a month. It has long been known that such glycerolated cords can confer immunity on animals (Rodet and Galavielle, 1901 *c*, Galavielle and Martin, 1902, Rodet, 1924)

Recently some modification of the older methods has been necessitated owing to the increased susceptibility of certain strains of *virus fixe* to glycerol Thus, Grysez (1937) of Lille recommends that the course be begun with cords preserved at +23° C for 9 to 16 days, and continued with cords glycerolated for 1 to 8 days As Oláh (1938) has reported that *virus fixe* is more resistant to phenol-glycerol than to glycerol it is possible that some such method of attenuating the virus may be introduced

(*b*) *Funayama's (1934) modification* This worker used an intensive course which began with 5-day cords and ended on the 18th day with a 1-day cord

(*c*) *Nicolle's modification* (see Marie, 1927 *b*). The treatment consists of 3 courses of injections.

World use of desiccated cord method.

Dried and glycerolated cord methods are extensively used in France, the French colonies, and other French-speaking countries, also in Alexandria, Bangkok, Berne, Brazil, Argentine, Chosen, Montevideo, Rio de Janeiro, Tokio, Poland

A report of the year's work of the Pasteur Institute of Paris appears yearly in the *Annals de L'Institut Pasteur* (60, 661; 62, 661; 64, 565; 66, 483; 68, 545; 69, 371, 71, 34, 294, 72, 952; 73, 1191).

Method 9 (*b*), dried cords plus Fermi's vaccine, is used in Buenos Aires (according to McKendrick, 1940).

2. Hoegyes's Method

Experimental. This method was introduced by Hoegyes in 1887 (see also [illegible] injections [illegible] last for a [illegible] ubinfective dilutions and gradually increased the strength until fully virulent doses were administered. Hoegyes's original dilutions were usually fully infective up to 1·200, 1.5,000 might be infective, while 1.10,000 was not infective. Weaker dilutions do not kill the animal more slowly than stronger, if the animal dies at all following injection of a dilution it does so in the usual time (Remlinger, Palmowitch, and Bailly, 1931 *d*) We, however, have noted a considerable prolongation of the incubation period, especially in guinea-pigs injected with weaker dilutions. The following correspondence has been observed between the infectivity of dilutions and desiccated cords (see Marie, 1927 *b*)· 1 10,000–1·6,000 dilution corresponds to 14- to 8-day cords, 1.5,000 to 7-day cords, 1·1,000 to 6-day cords, 1·500 to 5-day cords, 1 200 to 4-day cords. It should be noted, however, that certain strains have been found to show a greatly increased infectivity after many years' passage, and it is probable that these original figures are now inaccurate.

This method of treatment has been widely used in human practice and has proved very efficacious. Webster (1939 *b*) found the method to be effective in immunizing mice

Human inoculation The numerous modifications in dosage which this treatment has undergone since its inception need not be detailed, and Marie [illegible]

3–6. Phenol Methods (Modifications of Fermi's Method)

These vaccines have been very widely adopted in antirabies practice The virus may sometimes be definitely killed by the antiseptic, in other cases the vaccine contains attenuated virus

The effect of phenol on fixed virus The lethal effect of phenol on *virus fixe* had been known for many years before phenolized vaccines were actually introduced (see, e g, de Blasi and Travalli, 1890) The originators of the various methods (*vide infra*) have all studied the effect of phenol on fixed virus (see also Sawtschenko, 1911, Cumming, 1914) Although there is a certain amount of variation in their findings, it appears that in 0 5 per cent phenol a 1 per cent dilution of virus remains viable for at least 20 days at 20° C, 1 per cent. phenol will destroy a 1 to 2 per cent suspension of infected brain in 4 to 7 days at 20° C. (Semple, 1911). At 37° C. 1 per cent phenol will destroy up to an 8 per cent. suspension of virus in 24 hours (Semple), and a 20 per cent suspension in 144 hours (Stuart and Krikorian, 1929–30) Habel (1940 *b*) who worked with 31 strains of *virus fixe*, obtained somewhat different results At 37° C. he found that while some strains were destroyed

by 1 per cent. phenol in under 24 hours, others were still viable after 4 days He found that the longer the strain resisted phenol the greater the immunizing capacity.

Phenolized vaccines are prepared by adding phenol, usually 1 per cent, to infected brain tissue and leaving in the 37° C. incubator for about 4 days. At this stage, Habel (1940 *b*) found that most vaccines still contain viable virus The vaccines are then usually diluted to contain 0.5 per cent. phenol, and stored in the ice chest. Habel (1940 *b*) did not find any viable virus after 2 months storage

It appears that in the U S A. a number of phenolized vaccines exposed for sale for the treatment of man has been devoid of immunizing potency when tested in mice (Webster 1939 *b*).

Keeping properties. One of the great advantages of these vaccines is their keeping properties. For instance, it was found (Gloster *et al*, 1925–6) that carbolized vaccine retained a high degree of immunizing potency whether kept in the cold room or at shade temperature in Rangoon (approx. 87° F.) Vaccine was found to remain potent for at least 7 months after storage in an ice-chest in the plains of India in the summer (Covell *et al*, 1936–7).

3. Killed Phenol Methods

(*a*) *Semple's* (*1911*) *modification.*

Experimental. This method was originally introduced for use in India, and has been widely adopted in many parts of the world. For use as a vaccine, an 8 per cent dilution of brain in 1 per cent. phenol in normal saline is incubated for 24 hours at 37° C, and then diluted with normal saline to make a 5 per cent. dilution The vaccine is kept at room temperature for at least 30 days before use (*Report*, 1938–9)

Semple was able to immunize monkeys, dogs, and rabbits by subcutaneous injections of his vaccine Webster (1936) carried out a series of experiments in which he showed that mice could also be immunized by intraperitoneal injection. Habel (1940 *b*) examining the immunizing capacity in mice of phenolized vaccines prepared from 31 strains, found that 12 were quite ineffective, 10 moderately efficient, and 9 strains immunized against at least 2000 MLD

Human inoculation. Semple's vaccine (5 per cent. brain in ½ per cent phenol) has been widely used, both in India and elsewhere The dosage recommended by the Pasteur Institute at Kasauli depends on the Classification of Risk (see p 870) and is as follows Class I, all cases, 2 c.c. daily for 7 days, II, 5 c c for 14 days, III, adults, 10 c c daily for 14 days, children, 5 c.c. daily for 14 days (Webster, 1944).

World use The method is in use in West Africa, Ankara, Baghdad, Bangkok, India, Brazzaville, Roumania, Ceylon, Poland, Hong Kong, Malaya, Lisbon, Kenya, U S A, Canada, Palestine, Burma, Chile, Cuba, Shanghai, Teheran (McKendrick, 1940).

(*b*) *Stuart and Krikorian's* (*1925*) *modification*

This vaccine is a slight modification of Semple's, containing less nerve tissue It consists of a 2 per cent emulsion of virus-infected brain killed by 1 per cent. phenol at 37° C for over 24 hours. Before use it is diluted with equal parts of normal saline. Experimentally, rats and rabbits have been protected by this vaccine For human use, 5 c c is injected daily for 14 days intracutaneously in the abdomen This method has been widely used in Palestine (see Stuart and Krikorian, 1929–30).

(*c*) *Phenolized vaccines and antirabic serum*

It has been suggested that antirabic (sheep) serum be used along with carbolized vaccines (Shortt *et al*, 1934–5)

4. Live Phenol (Puntoni's) Method

In Puntoni's method the infected nervous tissue is ground up with 1 per cent. phenol (1921 *a*, *b*, 1923, 1928). After about a week at 21° C. this suspension is avirulent Doses of increasing virulence are inoculated, and from 40 to 100 injections may be given

Puntoni's method is used in Florence and Brazil

5, 6, 9 *b*. Fermi's Method (see Fermi, 1909 *a*, *b*, *c*, 1925, 1934)

In Fermi's original method (5) *virus fixe* was treated with 1.0 per cent. phenol, which was said to sterilize a 5 per cent virus suspension. Babès and Bobes (1908) found, however, that such treatment might fail to destroy the virus The usual course of treatment comprises daily injections of 5 to 6 c c. for 3 weeks. In Fermi's serovaccine method (6) antirabic serum is combined with virus Fermi's method is sometimes employed as an adjuvant to the desiccated cord method (9 *b*).

Fermi's original vaccine is used in Buenos Aires, Czechoslovakia, Egypt, Budapest, Dakar, U.S S R , Mexico, and Bolivia

Fermi's serovaccine has not been used since 1934

Lépine and Sautter's (1937) modification.

These authors have recommended a vaccine consisting of a 5 per cent. rabbit brain suspension in 1 per cent. phenol-water. The vaccine may be used after 24 hours' attenuation at 20 to 21° C, it may be stored on ice for 2 months without significant loss of potency. Rabbits could be effectively rendered resistant by such a vaccine The method is used in Beirut and Teheran (Lépine, 1946), and in association with Pasteur's method in Paris, Algiers, Hanoi, Saigon, and Antanarivo

Advantages of Phenolized Vaccines

Phenolized vaccines are very widely used throughout the world Their advantages have been summarized as follows (Remlinger and Bailly, 1936 *d*)

(*a*) They are easily prepared in the laboratory, with a minimum of apparatus (see Lépine, 1937).
(*b*) As dog or sheep brain may be used, fewer animals need to be sacrificed than in the desiccated cord method
(*c*) The antigenic potency is conserved for several months
(*d*) The vaccine is easily rendered sterile, and it is simple to carry out appropriate bacterial sterility tests.
(*e*) A considerable reserve stock of vaccine of guaranteed and lasting potency can be maintained (see also Zeuner, 1943).
(*f*) The vaccine is readily transportable, and treatment can thus be decentralized Patients may, therefore, be treated earlier and saved a long journey to a central institute.
Carbolized vaccine is very useful for bodies of troops far from a Pasteur Institute (see, e g , Hamerton, 1922).
(*g*) Any medical man equipped with a syringe and needle can inject the vaccine, without special technical skill
(*h*) Phenolized vaccines produce the minimum number of cases of neuroparalytic accident.
(*i*) The tissue can be mechanically ground, thus producing a true emulsion.

7. Heated Nerve Tissue Methods

These methods are often known after the names of Babès and Puscariu (see, e.g , Babès, 1912 *a*, Puscariu and Lebell, 1914, Téodorasco, 1923 *b*) Heating destroys or attenuates virus according to the temperature employed. Puscariu and Vesesco

(1895) showed that heat-killed virus was still antigenic, and animals have been immunized by courses of such heated vaccines. At first the course was begun with cords heated to 80° C., and although these were noninfective, they were still antigenic (Babès and Lepp, 1889). The treatment was continued with cords heated to 75° C., 60° C., 55° C, 50° C, and 45° C; on the last day unheated cords were given. Later (after 1908) only cords heated at 65° C. were used.

Another modification of the heated cord method is the one used at the antirabies centers in Cluj (Roumania), as described in 1935 by Botez (see Botez and Albon, 1929, also Botez, 1930).

The heated cord methods are used in Roumania, sometimes combined with serotherapy (Proca and Bobes, 1940).

8 and *9 a*. Etherized Vaccines

Etherized vaccines have been used extensively in antirabies treatment (Alivisatos, 1922, 1926, Hempt, 1925; Busson, 1925, Da Silva, 1926 a). Remlinger (*1918 a*) was the first worker to suggest the use of this type of vaccine. As usually employed, these vaccines contain attenuated but not completely killed virus. Zeuner (1943) has shown that the ether content, although sufficient to destroy nonsporing bacteria may not destroy sporing organisms.

The effect of ether on fixed virus. Remlinger showed that after 120 hours in sulfuric ether, the brain of an infected rabbit was rendered quite avirulent Alivisatos (1922) reported that virulence was lost after 140 hours. Virulence is lost from the periphery inward, the center of the brain remaining virulent longest Thus, Remlinger (*1919 c*) found that the periphery had lost its infectivity in 16 hours while the center did not do so for 120 to 125 hours Correspondingly, the smaller the piece of brain immersed the quicker is virulence lost (Iyengar and Beer, 1930–1). Cords lose their virulence in ether very much more quickly than brains, being usually avirulent in under 12 hours. To render etherized vaccines avirulent phenol is sometimes added Virus is destroyed when 1 per cent. phenol is added to a brain that has been 72 hours in ether, and incubation carried out at 37° C (Iyengar and Beer, 1930–1).

Varying ether resistance of different strains. A particular study of the comparative resistance of the Pasteur Institute (Paris) and Indian strains of *virus fixe* has been made by workers in India (Cornwall and Beer, 1925–6 *d*, Cunningham, Nicholas, and Lahiri, 1926–7, 1928, 1928–9 *b, c*). They found that the Paris strain was resistant to ether and was not destroyed under 168 hours' immersion. With Kasauli strain K2 destruction of virus occurred after 84 hours. The classical Kasauli strain was usually destroyed or markedly attenuated after 36 hours' immersion, although destruction did not invariably occur after 84 hours It is evident, therefore, that Kasauli strains are much more easily destroyed by ether than the Pasteur Institute (Paris) strain

Antigenicity of etherized vaccines Animals have been rendered resistant by inoculations of virus attenuated by ether (see, e g, Remlinger, *1919 c*). It has been noted that, although Berkefeld filtrates of rabies virus immunize rabbits (Remlinger, *1903 a*), this property is lost when ether is added (Remlinger, *1919 c*)

Human inoculation Hempt's (1925) method (8) was once used quite extensively, etherized virus being diluted 1 60 in saline. In mild cases 1 to 2 gm were inoculated, and 3 to 4 gm in severer cases, injections were given twice daily for 4 to 6 days This method was later superseded by a killed ether (carbolized etherized) vaccine

The treatment is used in Yugoslavia and Prague

Alivisatos's (1922) method (9 *a*) This method is not widely used, the vaccine consisting of *virus fixe* treated with ether for 72 to 84 hours As Alivisatos found that the infectivity of brain was only destroyed after 140 hours in ether, the method evidently employs attenuated virus

At the present day Alivisatos's method is used in severe cases as an adjuvant to the dilution method, in Athens and Vienna and certain Bulgarian institutes (see McKendrick, 1940). Method 9 (*c*), Alivisatos's method plus Fermi's method, is used in Salonica.

10. Yatren Method

A vaccine prepared from nervous tissue treated with yatren was introduced by Abadjieff (1928, 1932). Okuwada (1933) has used the vaccine experimentally. Fixed virus was destroyed by 5 per cent yatren in 3 hours at 37° C. In vaccine preparation a 10 per cent emulsion of brain in 4 per cent yatren was incubated for 24 hours at 37° C, before use it was diluted 1 in 4 and filtered.

B. VACCINES LESS WIDELY USED

Vaccines Containing Virulent Virus

1. *Ferran's method* An intensive treatment was recommended by Ferran (1888), who gave daily injections of virulent bulb in water.

2. *Cumming's (1914) method* In this method a homogeneous brain suspension was dialyzed against running (distilled) water. Injections of this dialyzed vaccine rendered rabbits resistant to 8 MLD of *virus fixe* injected intracranially. This vaccine was used in the United States of America, 2 c c being injected daily for 15 to 25 days. An anaphylactic reaction often occurred on the 7th or 8th day.

3. *Harris's method* (1912, 1913 *a*, *b*) Harris found that the infectivity of rabies virus could be preserved for a considerable time by freezing the brain and cord of a rabbit with carbon dioxide snow or liquid air, and drying *in vacuo* Infectivity was also preserved for several months by drying *in vacuo* at −18° C For use as a vaccine, tissue frozen with CO_2 snow was pulverized in a mortar, dried *in vacuo* over sulfuric acid, sealed and stored in the ice chest. At −10° C. no loss of infectivity occurred for at least 2 years.

Writing in 1921 D'Aunoy reported that this method had been in use in New Orleans for 6 years Adults were given 11 doses totalling 17,750 minimal infecting doses of virus preserved by freezing In severely bitten persons, 15 doses totalling 25,750 minimal infecting doses were administered Webster (1939 *b*) found the method effective in mice

4 *Marie's method* (see, e g, 1927 *b*) In this method excess *virus fixe* is mixed with antirabic serum (sheep) The course is begun with daily subcutaneous injections of a mixture of 2 c c of a 1 10 suspension of virus and 4 c.c antirabic serum; on the 5th day the treatment is continued with 6-day desiccated cords

5 *Phillips's (1922) method* The rabbit's brain is removed and ground to a paste in a mortar, and glycerol is added so that 0 1 c.c. of suspension should contain 15 mg of fixed virus material This suspension is filled into glass ampules, which are placed in a test tube and stored in the cold for a few hours The mouth of the test tube is then packed with pyrogallic acid, and potassium hydroxide is added, the tubes are stored at −2° C to −4° C Virus remains living after this treatment, and is used for human inoculation after a 3-day course of dead *virus fixe* (phenolized) Lubinski (see Kraus, Gerlach, and Schweinburg, 1926), using a similarly prepared vaccine, gave 20 daily injections of 2 c c of various dilutions as follows 1st day—1 200, 2nd day—1 100, 3rd and 4th days—1 66, 5th and 6th days—1 40, 7th day—1 25, 8th to 10th days—1 66, 11th to 13th days—1 40, 14th day—1 25, 15th and 16th days—1 66, 17th to 19th days—1 40, 20th day—1 20 Various modifications of this method are in use in the USSR

6 *Proescher's method* (1909, 1911) A number of cases was treated with unchanged *virus fixe* The brain of an infected rabbit was preserved on the surface of a 50 per cent glycerol agar slope, when required an emulsion was made and

(1895) showed that heat-killed virus was still antigenic, and animals have been immunized by courses of such heated vaccines. At first the course was begun with cords heated to 80° C, and although these were noninfective, they were still antigenic (Babès and Lepp, 1889). The treatment was continued with cords heated to 75° C, 60° C, 55° C., 50° C., and 45° C.; on the last day unheated cords were given Later (after 1908) only cords heated at 65° C. were used.

Another modification of the heated cord method is the one used at the antirabies centers in Cluj (Roumania), as described in 1935 by Botez (see Botez and Albon, 1929; also Botez, 1930).

The heated cord methods are used in Roumania, sometimes combined with serotherapy (Proca and Bobes, 1940).

8 and *9 a*. Etherized Vaccines

Etherized vaccines have been used extensively in antirabies treatment (Alivisatos, 1922, 1926, Hempt, 1925; Busson, 1925; Da Silva, 1926 *a*). Remlinger (1918 *a*) was the first worker to suggest the use of this type of vaccine. As usually employed, these vaccines contain attenuated but not completely killed virus. Zeuner (1943) has shown that the ether content, although sufficient to destroy nonsporing bacteria may not destroy sporing organisms

The effect of ether on fixed virus Remlinger showed that after 120 hours in sulfuric ether, the brain of an infected rabbit was rendered quite avirulent. Alivisatos (1922) reported that virulence was lost after 140 hours Virulence is lost from the periphery inward, the center of the brain remaining virulent longest. Thus, Remlinger (1919 *c*) found that the periphery had lost its infectivity in 16 hours while the center did not do so for 120 to 125 hours. Correspondingly, the smaller the piece of brain immersed the quicker is virulence lost (Iyengar and Beer, 1930–1). Cords lose their virulence in ether very much more quickly than brains, being usually avirulent in under 12 hours. To render etherized vaccines avirulent *phenol is sometimes added Virus is destroyed when 1 per cent. phenol is added to* a brain that has been 72 hours in ether, and incubation carried out at 37° C (Iyengar and Beer, 1930–1).

Varying ether resistance of different strains. A particular study of the comparative resistance of the Pasteur Institute (Paris) and Indian strains of *virus fixe* has been made by workers in India (Cornwall and Beer, 1925–6 *d*, Cunningham, Nicholas, and Lahiri, 1926–7, 1928, 1928–9 *b, c*). They found that the Paris strain was resistant to ether and was not destroyed under 168 hours' immersion. With Kasauli strain K2 destruction of virus occurred after 84 hours. The classical Kasauli strain was usually destroyed or markedly attenuated after 36 hours' immersion, although destruction did not invariably occur after 84 hours It is evident, therefore, that *Kasauli strains are much more easily destroyed by ether than the Pasteur Institute* (Paris) strain

Antigenicity of etherized vaccines Animals have been rendered resistant by inoculations of virus attenuated by ether (see, e g, Remlinger, 1919 *e*) It has been

inoculated, and 3 to 4 gm in severer cases, injections were given twice daily for 4 to 6 days This method was later superseded by a killed ether (carbolized etherized) vaccine.

The treatment is used in Yugoslavia and Prague.

Alivisatos's (1922) method (9 *a*) This method is not widely used, the vaccine consisting of *virus fixe* treated with ether for 72 to 84 hours As Alivisatos found that the infectivity of brain was only destroyed after 140 hours in ether, the method evidently employs attenuated virus

(*d*) When they wane, the titer can be increased by only a few more injections of cord.
(*e*) They found that the longer the course of treatment, the more pronounced the rabicidal power of the serum Correspondingly, the less desiccated the cords the higher is the rabicidal titer.

There is no definite unanimity with regard to the relationship of the rabicidal antibody to the protection acquired against rabies. It seems safe to conclude, however, that while protection and antibody formation usually occur together, this is not invariable. Thus, a person may be protected against rabies and yet show no

THE BLOOD DURING ANTIRABIES TREATMENT

Blood changes appear to be variable. Certain workers have referred to a leukopenia (Carvalho, 1922; Leger, 1923; Jonnesco, Valter, and Teodasiu, 1927), while others refer to a leukocytosis usually involving neutrophils and eosinophils, but sometimes lymphocytes and monocytes (Dodero and Hoang-Tich-Try, 1940). Some say the Arneth count is shifted to the right, others to the left.

Dodero (1940*b*) found that both upper and lower limits of fragility were usually lowered Heterophil hemagglutinins may develop (Rosenfeld and McDaniels, 1939).

MODE OF OPERATION OF ANTIRABIES TREATMENT

Curiously enough, th
important point: how
by Remlinger (1907*a*)
after it has reached the central nervous system. On the other hand, it may be that the injections serve to prevent the virus from reaching the central nervous system, certainly there would appear to be time to arrest the intraneural spread of virus,
may be
devel-
ijection
of animals with virus does not appear to confer immunity with any regularity, it would seem, nevertheless, that antirabies immunity is a tissue immunity. The cells of the central nervous system must, in some way, be rendered resistant to the rabies virus. It will be recalled that Negri bodies are less commonly found in treated persons who develop rabies than in untreated (Busson, 1930) It is possible that the interference phenomenon may be responsible for antirabic immunity. The susceptible cells may be "blocked" by the living particles of *virus fixe*, or inactivated particles, depending on the type of vaccine. When the street virus reaches the nervous system, it finds the susceptible cells already occupied. Or it is possible that the phenomenon of Magrassi (see Ch. XVII) may be concerned, the meeting of the two viruses in the brain leading to mutual extinction

DECENTRALIZATION OF ANTIRABIES TREATMENT

Patients bitten by a rabid or suspectedly rabid animal must be subjected to antirabies treatment as soon as possible. In countries where there is adequate and reasonably rapid means of transport, it is probably best to send the case to a central institute Here the patient can be treated by experts who devote their whole time to the treatment. Indeed, certain methods of treatment can be carried out only

0.01 gm. of brain tissue injected. In 5 days 0.05 gm. of virulent *virus fixe* was injected

7. *Krasmitski's (1902) method.* In this method filtered and diluted virus was heated to 37° C., and thus presumably slightly attenuated.

Vaccines Containing Dead Virus

1. *Lipovaccine.* It has been reported that the emulsification of virulent virus material in olive oil renders it avirulent. The emulsion is still antigenic, however (Botafogo Gonsalves, 1925).

2. *Formol method.* Cumming (1914) showed that 0.08 per cent. formaldehyde destroyed the virus in 2 hours. Formolized vaccines do not appear to have been widely used by public institutes, although they are supplied commercially in the United States Tzekhnovitzer and Goldenberg (1930) found formolized vaccines antigenic in experimental work. Shortt *et al.* (1937) showed that a formolized vaccine was as potent as a carbolized, in a series of animal experiments, while Jacotot *et al.* (1938) found, using guinea-pigs, that such vaccines were actually superior to phenolized vaccines. van Stockum (1938, 1941) recommended a 10 per cent. suspension of monkey brain formolized (1.5 per cent.) after incubating at 37° C. for 5 days.

3 *Purified vaccines.* Kaiser (1943) recommends a vaccine treated with ether to remove nonvirus nervous tissue, the virus being exposed later to iodine vapor. Veeraraghavan (1941) has purified sheep brain vaccine by iso-electric precipitation.

4. Sellers' (1923) vaccine was diluted, glycerolated, and phenolized.

The Use of Serum in Antirabies Treatment

Following the bite of a rabid animal, street virus probably remains at the site of the wound for a short time before invading the nervous system. When vaccines are given, even at once, there is bound to be a delay of several days before resistance develops It would, therefore, appear to be logical to administer antirabic serum locally and generally as soon after the bite as possible, to neutralize the virus before it can invade The results of serum treatment of experimentally infected animals have been most satisfactory (Habel, 1945, see p. 852). Antirabic serum should be combined with a course of active immunization (Shortt *et al*, 1934–5, Habel, 1945) Proca and Bobes (1940) have used serotherapy quite extensively and claim beneficial results They find that serotherapy tends to prolong the incubation period in cases that do develop rabies despite treatment. They accordingly suggest that a 2nd course of vaccine treatment be given about 2 months later

DEVELOPMENT OF RABICIDAL PROPERTIES IN THE SERUM AFTER ANTIRABIES TREATMENT

Many workers have recorded the development of rabicidal antibodies in the serum after a course of antirabies treatment (e g, Kraus and Kreissl, 1902, Semple, 1908, Kostrezewski, 1920, Puntoni, 1921 *a*, Nikolajewa, 1925, Alivisatos, 1926, Da Silva, 1926 *a, b, c*, Stuart and Krikorian, 1931–2, Webster, 1936). The development of these properties has been particularly studied after treatment with desiccated (or glycerolated) cords, and phenolized or etherized virus.

The findings of later workers, such as Cruveilhier and Viala (1937) and Dodero (1937 *a*), serve to corroborate the observations of many earlier workers, and are as follows

(*a*) After treatment with desiccated cord, rabicidal properties are found to develop in the serum

(*b*) These antibodies do not usually develop till about 10 days after the close of the antirabies treatment

(*c*) They remain present for up to 7 months

Incubation Period of Rabies in Treated Cases

Approximately one-third of cases develop their illness less than a month after the bite, one-third between 1–2 months, and the remaining third after 2 months. It has been stated that antirabies treatment may actually bring about death from rabies after a shorter incubation period than in untreated persons, as if *virus fixe* inhibits the defense mechanisms, and accelerates the passage of the street virus (see review of Proca and Bobes, 1940).

It has been suggested that rabies may develop in treated persons after an emotional "shock," as if the street virus was lying "latent" in the nervous system (Remlinger, 1945, 1946 *b*).

Cases of rabies developing after long incubation periods are said to be commoner when serum is used in treatment (Proca and Bobes, 1940).

Assessment and Presentation of Mortality Rates

The assessment of mortality from antirabies treatment. At first sight, it might appear that it would be a comparatively simple matter to record fatalities from antirabies treatment by following up all treated cases to see whether or not they remain in health. While this may be easy in European countries, it is extremely difficult in the East In India, for example, the patients return home after treatment, and it may be difficult to trace them again In the first year of operation at Kasauli, follow-up returns were received from 76 per cent. of treated patients, but in 1925 from only 30 per cent. On the introduction of improved methods, 80 per cent. of patients were followed up, and this resulted in a detection of more than double the previous number of deaths (Cunningham and Malone, 1930). Again, should a person die after antirabies treatment, it is possible that the attending doctor who signs the death certificate may be quite unaware of this fact and sign the certificate marked with some other cause of death There is no doubt that a proportion of fatalities after antirabies treatment is not recorded.

The presentation of rabies mortality rates. A practice that used to be adopted by antirabies institutes was to give what they called the "failure rate" These were cases in which rabic symptoms developed within about 15 days after the termination of the treatment. This rate is fallacious, as the shorter the treatment, the less cases will develop within this 15 days, conversely, the longer the treatment, the more cases will be included. It is far more accurate to give the total mortality rate, including all cases dying from rabies within 12 months of the cessation of treatment.

Work of van Stockum

van Stockum (1935, 1938) attempted to assess the value of prophylactics by comparing the percentage of cases with short incubations to the total number of cases She based her conclusions on a statistical analysis of deaths, and thus considered only those actually at risk She concluded that a vaccine from monkey brain was the most effective Greenwood (1945–6) examined her arguments, and concluded that there was no justification for her condemnation of methods other than her own

League of Nations Reviews

From the time of the First International Conference on Rabies in Paris (1927) till his death in 1943, Colonel A. G McKendrick analyzed the statistics submitted to the League of Nations in a series of Statistical Reviews (McKendrick, 1930, 1932 *a*, *b*, 1933, 1934, 1935, 1937, 1938, 1940). He analyzed the figures relating to 1,061,707 treated persons, of these persons 3,540 died of rabies, giving a mortality of 0.33 per cent.

After Colonel McKendrick's death, returns were analyzed by the scientific

Far East, communication may be very slow, and at any rate distances great. In such places decentralization affords the best method of securing rapid and efficient treatment for all persons bitten. In these circumstances phenolized virus is undoubtedly the method of choice. All that is required is a suitable consulting room equipped with an ice-chest and facilities for administering injections in an aseptic fashion. The physician-in-charge does not require to be a whole-time expert, although he must be trained in antirabies methods and able to recognize the first signs of neuroparalytic complications.

With regard to decentralization, Cunningham and Malone (1930) emphasized the important point that in India, if there is no decentralization, only a fraction of persons at risk is actually treated They made the following recommendations

1. Decentralization of treatment should be carried out for Classes 1 and 2 (Hempt).
2. Classes 3 and 4 should be treated at a central institute.
3. Success depends on an accurate classification of risk, and Classes 3 and 4 must be dispatched speedily to Kasauli.

For further information on the work of the Kasauli Institute and its out-stations, see Webster (1944).

DETERMINATION OF THE RELATIVE EFFICACY OF VARIOUS METHODS

It will be evident that there is a large number of different methods of antirabies treatment in use throughout the world, and the question arises How do they compare with one another in immunizing efficiency?

This problem can be approached from two aspects. the experimental and the statistical. With regard to the first, the usual method of testing the potency of vaccines is to immunize animals, and later subject them to a test injection of virus

This question has been fully discussed in the previous chapter. It will be recalled that experimental work has amply demonstrated that animals can be immunized with potent strains, so that they withstand a subsequent test dose of active virus Live and chemical vaccines (phenol-, formol-, chloroform-, ether-, treated) have all been shown to be effective under these conditions. The most effective are known to be irradiated brain tissue vaccines or tissue cultures. When antirabies vaccines are given to animals after infection, it has been found difficult to secure protection, although very large doses have some effect Irradiated vaccines have proved very much more effective As far as experimental work goes, it suggests that the commonly used types of vaccine are not particularly potent immunizing agents, and not as efficient as the newer irradiated vaccines No striking superiority of any of the older types of vaccine has been definitely demonstrated by experimental studies

An elaboration of the experimental approach is to immunize human cases with various types of vaccine, if possible, the cases to be treated with each type of vaccine should be chosen strictly alternately For instance, such experiments were carried out by Cunningham, Malone, and Craighead (1933) using carbolized, Alivisatos's, and ether-carbolized vaccines Another method of assessing the relative efficacy of various treatments will now be described, viz, the study of mortality rates in treated cases

MORTALITY FROM RABIES IN TREATED CASES

Despite the application of antirabies treatment, a number of patients, none the less, dies of rabies

(*b*) Licks on intact mucosae of mouth, nose, eyes, anus, or genito-urinary tract.
(*c*) Bites or scratches raising epidermis but not drawing blood, except on head, neck, or fingers

Class 2. (*a*) Licks on fresh cuts on fingers
(*b*) All bites and scratches on fingers which are not lacerated, not over ¼" long and have not penetrated true skin
(*c*) Bites and scratches on all parts of the body except head, face, or fingers, definitely drawing blood, but excluding bites 5 or more in number or in which extensive laceration has occurred.
Any case in this category 14 days or more late in commencing treatment will be treated as for Class 3.

Class 3. (*a*) Licks on fresh cuts or abrasions on head or neck.
(*b*) All bites or scratches on head and neck.
(*c*) Bites or scratches on fingers which are lacerated, over ¼" long or have *penetrated true skin*
(*d*) All bites penetrating the true skin and definitely drawing blood when there are 5 or more in number
(*e*) All bites on any part of body causing extensive laceration.
(*f*) All jackal and wolf bites and licks

(*c*) *The position of the bite.* McKendrick (1940) found that the mortalities for Europeans and non-Europeans according to the position of the bite were as follows

	Europeans	*Non-Europeans*
Head	1.29	3.41
Arm	0.15	0.53
Trunk	0.02	0.22
Leg	0.05	0.27

The mortalities for Europeans bitten on the head, arm, trunk, and leg were in the ratio of 100·12 2 4, while for non-Europeans the corresponding ratios were 100.15:6 8.

(*d*) *The intervention of clothing* McKendrick (1938) reported that in the case of Europeans bitten on the bare skin, the mortality was 8 times that in those bitten through clothing; for non-Europeans it was 3 3 times as great for those bitten on the bare skin as through clothing.

(*e*) *Delay in commencement of treatment.* McKendrick (1940) found in the

cent. died

The detailed figures are

Time of Arrival	*Mortality* Non-European	European	*Ratio of Mortality* Non-European/European
0–4 days	0.47	0.19	2.5
5–7 days	0.47	0.10	4.7
8–14 days	0.50	0.07	7.1
over 14 days	1.08	0.12	9

It is probable that these figures do not point to a true racial susceptibility. It is more likely that the non-European arriving late is more at risk than the European.

There has been a number of recent reports referring to cases dying of rabies despite very prompt treatment, starting even within a matter of hours (Denison

ma-
all

staff of the Health Section of the League of Nations. This 10th (and final) review, presented in a paper by Greenwood (1945–6), referred chiefly to 1938 and 1939 with some figures up to 1944. Including figures supplied by the U.S.S.R., the 10 reviews referred to 1,670,848 treated persons.

Tables 34 and 35 give the figures relating to mortality in the 10th review and all 10 reviews. The mortality from rabies in treated European persons over the period of all the reviews is seen to be 0.15 per cent., and in non-Europeans 0.52 per cent.

Factors Influencing Mortality Rates

Mortality rates such as have been quoted in Tables 34 and 35 are dependent upon a number of factors; for the following information we are mainly indebted to the work of McKendrick and his coworkers (McKendrick, 1928, 1940, McKendrick and Fox, 1917; Harvey and McKendrick, 1923, 1930). We shall quote chiefly from McKendrick's last (9th) review, the figures for the 10th review being substantially similar.

(*a*) *The race*. This is by far the most important factor determining mortality from antirabies treatment. For the period covered by McKendrick's 9 reviews the mortality among non-Europeans was no less than 3.7 times as great as among Europeans (Europeans 0.15 per cent., non-Europeans 0.56 per cent.). Rabies mortality figures are, accordingly, usually given separately for Europeans and non-Europeans. In the 9th review, 53.5 per cent. of treated persons were Europeans, and for the period of all 9 reviews the percentage was 53.7 per cent.

It is unlikely that there is, however, a true racial susceptibility of the non-European. It is probable that as Europeans are usually bitten through clothing they are less at risk than non-Europeans. Also the statistics for Europeans are greatly "diluted" by the inclusion of large numbers who take treatment as a precaution, without being at risk.

(*b*) *The severity of the bite* influences the mortality as follows. In Europeans the mortality in deep bites was 6.5 times as great as in more superficial ones, whereas, in non-Europeans deep bites were only 3.3 times as serious as superficial (McKendrick, 1940). McKendrick (1928) gave the following information with regard to the mortality following bites, according to the number of tooth marks thus, after bites with only 1 mark the mortality was 0.31 per cent., with 3 marks 0.88 per cent., with 6 marks 2.22 per cent., and with 12 marks 4.76 per cent.

Hempt's (1925) classification has proved a useful method of estimating the severity of the bite and the degree of risk to which the person is exposed (see e.g., Cunningham and Malone 1930). *Four classes are recognized*

Class 1. These patients have not been bitten, but the saliva of a rabid, or suspectedly rabid, animal has gained access to cuts.

Class 2. These patients show superficial bites on the trunk or limbs (excluding fingers).

Class 3. (*a*) This class includes all superficial bites on the fingers.
(*b*) Here there are superficial bites on all parts of the body (not the head and neck), more extensive than in Class 2.
(*c*) In this class the patient suffers from deep bites in a few areas (not the head and neck).

Class 4. (*a*) Here there are deep bites all over the body.
(*b*) Any bite or scratch on the head and neck.

That this classification affords a fair estimate of the risk to which a bitten person is exposed is shown by the following figures of Cunningham and Malone (1930). with Class 1 bites, the mortality was nil, with Class 2, 0.31 per cent., Class 3, 1.04 per cent., and with Class 4 the mortality was 7.93 per cent.

Indian classification. The following classification was adopted in India in 1939 (Webster, 1944).

Class 1. (*a*) Licks, including direct contact with saliva, on fresh cuts except on head, neck, or fingers.

3. Cauterization is obviously of some value in protecting against rabies.

4. Rabies virus is an effective antigen, but certain strains have shown very feeble immunizing potency. Animals can be actively immunized especially with live, phenolized, chloroformized, and irradiated vaccines, so as to withstand a subsequent intracranial test dose of virus.

5. It is difficult to prevent rabies developing by injections of vaccine given after infection, but this has been secured by certain workers in small laboratory animals.

6. Various phenolized vaccines tested in the U. S. A. have been found to be almost inert in inducing active immunity. In the past, a considerable number of persons must have been treated with vaccines of very low or negligible immunizing activity.

7. Vaccines prepared by exposure of brain tissue to ultraviolet light have been shown to be the most effective immunizing agents in animals. These vaccines have not been used in man.

8. The mode of operation of antirabies treatment is unknown, but it may depend on the interference phenomenon.

9. Large numbers of persons treated with antirabies vaccines are not at risk. Owing to difficulties of "follow-up," numerous deaths from rabies after treatment are not so recorded. The published figures for mortality from rabies in treated persons are, therefore, fallaciously low.

10. It is only rarely possible to tell if any given treated person has actually been infected with rabies virus or not. Even if the biting animal is proved rabid, this does not mean that an infective dose of rabies virus has necessarily been deposited in the wound.

11. McKendrick's reviews do not point to the superiority of any one type of commonly used vaccine.

12. Mortality from rabies after treatment, as in the case of untreated persons, depends on the quantity of virus inoculated, and the amount of trauma caused.

We know that antirabies treatment can act in small laboratory animals, even when administered after infection. There is, therefore, every justification for expecting some benefit from the treatment in man.

Surprisingly few papers have been published of recent years bearing on the value of antirabies treatment in man, where adequate control untreated groups have been observed.

Cornwall (1923) stated that the only way to evaluate treatment is to take those instances where a presumably rabid dog has bitten several persons, some of whom are treated and some not. Both groups must be observed for several months. He gave these figures from S. India:

Total number of persons observed	2174
Number treated	812
Deaths among treated	2.9 per cent
Number untreated	1362
Deaths among untreated	6.2 per cent.

He therefore concluded that treatment saved one out of every two who would otherwise have developed hydrophobia.

Yu (1941) in China, observed 201 patients fully vaccinated after dog bites, of whom 9 died, giving a mortality of 4.5 per cent. Two of these cases started treatment late. In 182 unvaccinated persons there were 18 cases of rabies, giving a mortality of 10 per cent.

Taking both these sets of figures at their face value, it appears that antirabies treatment halves the mortality. In an attempt to obtain further information, we have communicated with M. Remlinger who kindly wrote at length, along the following lines (1946*a*):

methods of treatment, for persons bitten by dogs was 0.30 per cent., cats 0.04 per cent., wolves 8.70 per cent., jackals 1.48 per cent. For the same period, only 1 person died from the bite of a soliped (actually an ass). For the whole reviews, of 33,626 persons bitten by solipeds and ruminants, only 3 cases developed rabies. Of 11,134 persons who came in contact with human rabies, only 1 contracted the disease.

(g) *Evidence of rabies in biting animal.* The biting animal can be classified under various headings, according to the degree of certainty with which it is thought to be rabid. Category A—animal is proved rabid by experimental means, B—animal is certified rabid by medical or veterinary physician; C—animal is only suspectedly rabid, D—animal is not suspected of being rabid. It is evident that the persons bitten by animals in Categories A, B, and C will show a higher mortality than those in D. For example, McKendrick (1940) reported a mortality of 0.30 per cent. after bites from animals in Category A as compared with 0.009 per cent. in Category D, 0.18 per cent. in Category B, and 0.29 per cent. in Category C. The important dividing line is thus between Category D and the others.

Conclusions

McKendrick (1940) in summarizing his examination of statistics relating to approximately a million persons found little evidence of superiority of one method over another. He thought it unlikely that a difference in efficiency of more than some 25 per cent. existed between any two of the methods. There was, however, *the possible exception that method 9 (a) employing dilutions with, in severe cases, the addition of Alivisatos's vaccine might be superior to the others.*

Greenwood (1945–6), in his analysis of the whole 10 reviews of the League of Nations, came to the conclusion that there was no evidence enabling him to decide that any one method has a definite superiority over the others. He found that it is impossible to overcome the difficulties of comparing groups of treated persons in whom the degree of risk is unknown. It does not appear that any further compilation of data can throw any more light on the relative efficacy of the different treatments.

Before leaving this question of the relative efficacy of various methods of treatment, we would like to impress one point upon the reader: although the above-quoted observations may not suggest the superiority of any one method, there is another factor to be considered. That is, after any type of vaccine the patient may develop a serious accident, and these are much less common with some types than others. For instance, McKendrick (1940) found that the incidence of accidents was less than 1: 8,000 in those treated by killed phenol, killed ether, and heated vaccines, 1: 3,398 in those treated by living cords, 1: 3,194 by dilutions, and approximately 1: 2,000 for those treated by methods 9 (*a*) or (*c*). It is this lower incidence of fatal accidents following killed vaccines, rather than any superiority in their immunizing capacities, that has prompted so many to abandon living vaccines.

THE VALUE OF ANTIRABIES TREATMENT IN GENERAL

From what has been said above, it will be evident that there is a large number of factors complicating the evaluation of antirabies treatment. This question has been discussed by one of us elsewhere, and the following remarks are largely quoted from this paper (Rhodes, 1946).

The main factors to be considered are:

1. The mortality from rabies in untreated persons bitten by rabid animals is on the average not more than 15 per cent., and may be as low as 5 per cent. The mortality figure varies directly with the amount of virus inoculated in the wound and the degree of trauma.
2. Strains of street virus probably vary in virulence and possibly in antigenic structure.

We question, however, whether in many institutes nearly as many as 500/1000 treated persons are actually at risk following dog bites. If only 100 are at risk, and the mortality in untreated cases is 10 per cent, then only 10 persons would die in our group of 1000 without any treatment.

One cannot, therefore, put forward a strong case in support of antirabies treatment by arguing on general lines, rather than from figures of more or less controlled series such as that of Cornwall.

When we come to discuss the position in the much severer wolf bite, there seems to be more satisfactory evidence of the value of treatment. The mortality from untreated wolf bites, due to rabies, is generally believed to be not less than 60 per cent, and it is said to be very rare for wolves to bite unless rabid. Accordingly, of 1000 persons bitten by wolves practically all may be considered to be genuinely at risk—so that not less than 500–600 of the 1000 should die from rabies if untreated. The mortality from rabies in treated cases of wolf bite is not more than 15 per cent. (Remlinger, 1946 *a*). If one accepts the high mortality in untreated cases, and the statement that wolves seldom bite unless rabid, it would appear that antirabies treatment is of definite value.

We have also received a personal communication from Professor Lépine of the Pasteur Institute of Paris (1946), who firmly believes in the efficiency of antirabies treatment, and sees no reason for throwing suspicion on the value of the method.

In conclusion, on the evidence at present available, we regard antirabies treatment as being of some value in the prevention of rabies, although it may not necessarily act by the process of active immunization. There is no justification for withholding treatment from persons thought to be at risk. The treatment as at present employed could probably be considerably improved, partly by the greater use of immune serum, and partly by the greater use of more potent vaccines.

There is a wide field for further research, particularly into the mechanism involved in the acquisition of the immune state. It is most desirable that every effort should be made to secure statistical evidence concerning the value of antirabies treatment, by comparing the incidence of the disease in treated persons, and in those exposed to the same risk who for some reason have not taken treatment.

Let us consider 1000 persons treated in an antirabies institute for dog bites. Probably only 500 of these have been bitten by rabid dogs. As the death rate in such persons may be 15 per cent. we may expect 75 of the 1000 persons to die of rabies if untreated The mortality in treated persons is, however, only about 5 per 1000. By this line of argument it appears as if antirabies treatment saves 70 persons per 1000 treated.

2. They may suffer from a neuroparalytic accident, which may prove fatal. The exact etiology of this condition is still uncertain.

1. *Rage De Laboratoire*

The term *rage de laboratoire* was introduced in the early days and applied to certain cases which died after antirabies treatment. The term carried the insinuation that the treated person had been infected and died from the *virus fixe* in the injection that was supposed to save his life. There is no doubt that genuine cases of *rage de laboratoire* have occurred. In these, the patient has died following antirabies treatment with live vaccine, and it has proved possible to isolate *virus fixe* from the central nervous system (Bareggi, 1889, Athias and França, 1909–10, França, 1910, Remlinger, 1935 *a*, Proca and Bobes, 1940). Considerable interest has always been taken in this condition in France, and Remlinger (1935 *a*, *b*) has published a very complete review of the subject.

In many of these cases, the person has been bitten by a nonrabid animal, or may not even have come in contact with rabies at all (e g , Bareggi, Athias and França). This has led some persons to claim that all cases of neuroparalytic accident (*vide infra*) are due to *virus fixe*, i e , are cases of *rage de laboratoire* Such a theory cannot be generally accepted today, as neuroparalytic accidents have also followed the use of killed vaccine and, in animals, of normal nervous tissue.

Clinical features.

The following account of the symptoms of *rage de laboratoire* is taken largely from Remlinger's authoritative review The disease usually begins immediately after a course of antirabies treatment, or up to 40 days later. At the onset the patient is febrile and weak The lower limbs become completely flaccid, and there is retention of urine and feces, the paralysis spreads up to produce dyspnea, dysphagia, dysarthria, and cardiac irregularities There are no symptoms of hydrophobia.

Incidence.

The incidence of *rage de laboratoire* is distinctly low, probably not much over 30 cases have been recorded, but Remlinger (1935 *a*) believes that this figure gives a wrong conception of the true position. He thinks that many cases are missed owing to an inadequate "follow up" system, others are misdiagnosed or miscertified, while in others no autopsy or animal inoculation test is carried out.

Etiology.

To isolate the rabies virus from suspected cases of *rage de laboratoire*, a suspension of the bulb should be injected into a rabbit Supposing the animal dies from rabies these questions arise First, is the virus a street or a fixed strain? Second, supposing it is a fixed strain, what is the significance of its presence in the bulb?

Differentiation of street and fixed strains

Often the differentiation may not be a difficult matter. The paralytic symptoms in the inoculated rabbit may come on quickly, and there may be an absence of Negri bodies, both suggesting the [illegible]
toms in the rabbit may come o[illegible]
Negri bodies, thus indicating that [illegible]
but with an ordinary rabies due t[illegible]
ing between strains of *virus renfo*[illegible]
for, as they are seldom present ir[illegible]
may show the strain to be possess[illegible]
however, *virus fixe* is isolated, what does this mean?

CHAPTER LXXIX

REACTIONS AFTER HUMAN ANTIRABIES TREATMENT

A. BENIGN REACTIONS

General Systemic Reactions after Antirabies Treatment

VARIOUS minor disorders may develop during or after a course of antirabies treatment such as fever, headache, giddiness, insomnia, palpitations, and diarrhea. Cunningham and Malone (1930) recorded a case of generalized angioneurotic edema.

In a case described by Palmer (1941) there was constipation and lack of consciousness of the act of defecation.

A number of cases of sudden shock-like collapse or fit has been recorded, usually coming on towards the end of a course of treatment, it appears that these reactions are due to sensitization to protein contained in the vaccine, are commoner in persons giving a history of allergy, and can be largely avoided if smaller doses are given, desensitization can also be attempted (Dodero, 1938 *c*, Bernard, 1939, Horack, 1939, Lépine, 1939, Dorfman, 1940, Noury, 1940, Palawandow, 1940) It appears that this shock does not occur if the vaccine is prepared from dog or sheep brain instead of rabbit brain (Raynal and Lieou, 1946) A shock-like syndrome has been produced in rabbits by repeated injections of phenolized brain (Raynal and Lieou, 1940 *b*)

Albuminuria is said to occur in 10 per cent of cases (Auffret and Dodero, 1940 *a*).

Local Reactions after Antirabies Treatment

Local reactions of the skin after injection of antirabies vaccine have been recorded by various authors (*Cunningham and Malone*, 1930, *Lépine and Cruveilhier*, 1935 *a*, Cruveilhier *et al*, 1939) and by Remlinger (1927 *c*)

1 *Erythematous patches* This lesion usually develops about a week to 10 days after the beginning of antirabies treatment, when a few hours after an injection of vaccine an erythematous patch appears, which may measure some centimeters in diameter *This patch usually fades away after about 6 to 8 hours, only* to reappear after every subsequent injection The erythema usually becomes less marked with later injections, and after 15 to 16 may only be very slight. This type of reaction is more severe after the use of etherized vaccine than carbolized

2 *Urticarial reactions and rashes* These were found to occur in 16 per cent. of cases treated with etherized or carbolized vaccines (Cunningham and Malone).

3 *Abscesses* These develop only rarely and may be acute or chronic, they are due to an error in aseptic technique

It has been stated that if these local reactions occur in the first course of antirabies treatment, they may be much less marked, or even absent, in a second course (Kaktine, 1931) Cunningham and Malone, however, found that erythematous patches were more severe in those undergoing antirabies treatment for the second time It has been suggested that a functional liver disturbance is responsible for these reactions (Cruveilhier *et al*, 1939)

B. SEVERE AND FATAL REACTIONS

Patients may suffer from serious, often fatal, illnesses of two types after antirabies treatment, fortunately these are extremely rare

1 Persons may die of *rage de laboratoire* That is to say, the virus in the vaccine proves pathogenic, after death, *virus fixe* may be isolated from the brain

that the presence of this virus is not incidental, and that it is the definite etiological agent of *rage de laboratoire*.

We would emphasize that although *rage de laboratoire* is a very rare condition, it is a most tragic one, for it cannot occur if killed vaccines are used. It is probably largely for this reason that so many present-day workers prefer to use killed vaccines, in preference to living vaccines which have no greater immunizing powers.

2. Neuroparalytic Accidents

This term is applied to cases which develop certain neurological manifestations after undergoing a course of antirabies treatment. Similar accidents may also occur in animals (*vide infra*) The syndrome should be sharply delimited from neurological disorders produced by street virus (e g, the landriform type of rabies), and by fixed virus (*rage de laboratoire*), for neuroparalytic accidents are quite distinct from these. Cases of neuroparalytic accident do not show hydrophobic symptoms, pathologically they differ from rabies, no Negri bodies are found, and injection of brain yields no virus.

The condition has attracted much attention in the literature, especially the French. Remlinger (1905 *a*) published one of the earliest papers on the subject, in which he reviewed some 40 cases (see also 1908 *a*, 1927 *a*). Fielder (1916) reviewed some 13 cases. In reporting the proceedings of the First Conference on Rabies, Remlinger published another authoritative review on the question (1927 *b*). The slightly later paper of Stuart and Krikorian (1928) should also be consulted. Remlinger (1932) reviewed 66 cases occurring after his 1927 paper; later (1937 *a*) he reviewed 202 cases since 1932 Other papers of interest may be mentioned (Paulian *et al.*, 1939; Jones and Ellinger, 1940–1, Dang, 1941, Thomas, 1945, Sellers, 1947).

Clinical features.

Factors predisposing to neuroparalytic accidents. It has been recognized for a considerable time that certain persons are more prone to develop neuroparalytic accidents than others (see, e g, Babès, 1909 *a*, Report of Rabies Conference, see p. 800, Remlinger, 1927 *b*). These accidents are more frequent in brain workers than manual laborers, the patients are often nervous and "highly strung" Alcohol, syphilis, chill, fatigue, and traumata are also thought to have some predisposing influence

Incubation period The accident usually develops between the 13th and 15th day of antirabies treatment.

Symptomatology. Neuroparalytic accidents usually assume one of three forms (*a*) the Landry type, (*b*) the dorsolumbar paralytic type, and (*c*) a neuritic type often characterized by facial paralysis. At the Rabies Conference some 243 cases were reported, mostly falling into one or other of these groups Gordon (1935) has [illegible]

[illegible] ccident have been [illegible]) or (*c*) (Rendu, [illegible], 1932, Stuart and Krikorian, 1930, 1933, Ch'en and Ch'eng, 1936; Idei, 1937). Symptoms usually arise towards the end, or shortly after the completion, of the course of antirabies treatment. [illegible]

[illegible] stated to be about 30 per cent, and in the remainder recovery usually occurs rapidly. At the Rabies Conference 39 out of 243 reported cases fell into this group

(*b*) *The dorsolumbar type.* This form is less severe than the Landry type, and is the commonest type of neuroparalytic accident. The clinical features are ex-

The significance of virus fixe *in the central nervous system*

Does the presence of *virus fixe* in the human central nervous system mean that it is necessarily pathogenic? May not *virus fixe* be present in the brain of all cases treated by living or attenuated vaccines?

Quast (1926) claimed to have isolated a strain with properties suggestive of *virus fixe* from the bulb of a person subjected to antirabies treatment, who presented no clinical signs of rabic infection. Further, he treated dogs with rabies vaccine and demonstrated virus in the brain. Similar results were obtained in injected animals by Isabolinski and Zeitlina (1929). These observations suggested that the presence of *virus fixe* in the central nervous system of treated persons might be quite usual. Were these observations confirmed, it would cast serious doubt on there being such a condition as *rage de laboratoire* at all, the presence of *virus fixe* in the central nervous system being evidently a normal occurrence

However, much experimental work has been carried out in which these findings have not been substantiated. Thus cats, dogs, rabbits, and guinea-pigs were immunized by the desiccated cord method and with living *virus fixe*. When the animals were killed after some lapse of time no virus could be isolated from the central nervous system (Remlinger, 1910, 1927 *b*, Remlinger and Bailly, 1927 *a*, 1928 *b*, 1931 *a*; Schnürer and David, 1927; Burnet, 1928; Nicolau and Kopciowska, 1932 *b*, and see Report of Rabies Conference). No virus could be isolated by cataphoresis (Nicolau, Viala, and Kopciowska, 1930; Cruveilhier, Nicolau, and Kopciowska, 1935). Not even when the vaccines were prepared from the active Chisinau strain could virus be demonstrated in the central nervous system of injected animals (Remlinger, Palmowitch, and Bailly, 1931 *a*).

As Quast's observations have not been confirmed by the bulk of experimentalists, it is now generally agreed that *virus fixe* does not occur in the central nervous system without having some pathogenic significance. The next point to consider is, what evidence is there that *virus fixe* is sufficiently pathogenic for man to cause a fatal infection?

Virulence of virus fixe *for man*

A number of observations is on record which suggest the innocuity of *virus fixe* for man. Various persons have injected human beings with living or slightly attentuated fixed virus, subcutaneously and even intravenously, with no harmful results (Wissokowicz, 1902, Nitsch, 1904, Remlinger, 1935 *a*). Further, as Remlinger points out, although rabies has frequently been contracted by persons carrying out a postmortem on a naturally infected animal, the same accident has not befallen those working with infected passage animals in the laboratory.

Although tacitly assumed on the strength of the above experiments, the avirulence of *virus fixe* for man is not absolute Thus, a number of cases of rabies has followed the use of attenuated or virulent vaccines, *virus fixe* could be isolated from the central nervous system In these cases the possibility of naturally acquired rabies was ruled out as, although the person may have been bitten, the animal was proved to be healthy (see, e g, Ferran, 1888, Bareggi, 1889, França, 1910).

Other factors influencing the etiology.

Remlinger (1935 *a*) has stated that the method and site of injecting the vaccine is of importance Thus, if many nerve endings are traumatized, the virus may be able to ascend in the nerves more readily and cause rabic infection of the central nervous system He has also noted a tendency for the more intellectual classes to be affected, and for the cases to occur in small groups of two or three

Conclusions.

We may conclude that in certain, fortunately very rare, fatal cases following antirabies treatment with live vaccine, *virus fixe* may be isolated from the brain,

Of the 2 cases that complicated antirabies treatment, one had been bitten by a healthy camel, and the other had not been exposed to rabies at all

Histologically, all these cases presented marked evidences of widespread involvement of the ganglion cells in the cord The primary changes were nuclear, and the following types of reaction might occur. (*a*) the clear basophilic type of nucleus with somewhat coarse chromatin, (*b*) the dark basophilic type which was deeply stained, with prominent reticulum and chromatin bodies, and with or without a nucleolus, (*c*) the dark basophilic homogeneous type where the deeply stained nucleus was structureless All these types of nuclear change (but especially "*a*") might precede karyolysis. There was no demyelination or perivascular cuffing, and apart from some edema, the remarkable nerve cell changes were the only features

Relationship to other types of "postinfective" encephalomyelitis. Perdrau (1928), in an authoritative article on encephalomyelitis in general, concludes that the same pathological changes occur in true postvaccinal encephalitis, measles encephalitis, and rabies neuroparalytic accidents. Perivascular demyelination has, however, only rarely been found in cases of neuroparalytic accident. Undoubtedly when this occurs the picture closely resembles that of true postvaccinal encephalitis, but many reported cases have not resembled this condition. The etiology of postvaccinal encephalitis and related disorders is still *sub judice*, this subject is discussed elsewhere (see Ch XXXV).

Epidemiology and incidence.

Remlinger (1927 *b*) has given much information on this question (see also Stuart and Krikorian, 1928) Thus, children suffer much less commonly from neuroparalytic accidents than adults, the majority of cases being over 15 years of age. The sexes are equally prone to develop neuroparalytic accidents, although men are more predisposed to bites than women Intellectuals are more prone to attack than laborers, and Europeans may be more so than Eastern races, although this is not a general rule.

There appears also to be a distribution of neuroparalytic accidents according to the institute One institute using the same method as another institute may have a high incidence of neuroparalytic accidents, while the other escapes. Certain institutes, for example, the Pasteur Institute in Paris, seldom seem to have cases of neuroparalytic accident, although at others they are quite frequent.

Incidence of neuroparalytic accidents Remlinger (1927 *b*) is of the opinion that many minor cases of neuroparalytic accident fail to be reported and that the true incidence is higher than any published tables would lead one to suppose. He gives the following reasons why such understatements should occur (*a*) an imperfect "follow up" of treated cases, (*b*) other causes may be blamed for the paralysis, such as syphilis, alcohol, and influenza, (*c*) cases may definitely be concealed by official reporters.

We quote (Table 36) the figures given by Greenwood (1945–6) for the incidence of neuroparalytic accidents for the period since the Rabies Conference in 1927, according to the method of treatment

The incidence of neuroparalytic accidents in the main methods of treatment will now be discussed, referring both to Greenwood's figures and to the earlier reports of the Rabies Conference (Remlinger, 1927 *b*)

(*a*) The desiccated cord method gives a high percentage of neuroparalytic accidents (mainly nonfatal), although in the Pasteur Institute in Paris from 1911 to 1927, among 13,450 treated cases there was not one of this complication A week's treatment of cords in glycerol tends to reduce the incidence of neuroparalytic accidents

(*b*) Hoegyes's dilution method also gives a high incidence of neuroparalytic accidents, which are mainly fatal At the Rabies Conference it transpired that, although in Budapest the rate was low (0 39 per cent.), at Breslau it was 1 05 per

plicable by the presence of a dorsolumbar myelitis (Remlinger, 1905 *a*, 1927 *b*; Tartakoff and Vibber, 1932, Stuart and Krikorian, 1933; Marinesco and Draganesco, 1938). The patient may be slightly febrile, and feels weak, the lower limbs become paralyzed, usually with diminished sensation, and sphincter disturbances may occur. Although transient weakness may involve the upper extremities, there are never any of the severer bulbar symptoms. The fatality rate is not over 5 per cent. (Remlinger), the majority of cases recovering quickly.

At the Rabies Conference there were 68 out of 243 cases of paraplegia with sphincter disturbances, 33 cases of paresis of the lower limbs, with urinary retention, and 21 cases without retention.

(*c*) *The neuritic type.* The patient may be pyrexial, and usually shows a temporary paralysis of the facial, oculomotor, glossopharyngeal, or vagus nerves. At the Rabies Conference 58 out of 243 cases of facial paralysis were reported, and a few cases of paralysis of limbs and other cranial nerves. A case of double papilledema after antirabies treatment with carbolized vaccine has been recorded (Cormack and Anderson, 1933) also another case of optic neuritis (Koenigsfeld, 1945).

(*d*) *Other syndromes.* Gordon (1935) described cases with an abrupt onset, pyrexia, headache, and pains in the back, stiffness of the neck and Kernig's sign, increased reflexes, facial paralysis, and lymphocytosis in the cerebrospinal fluid.

The period of incapacity from neuroparalytic accident usually lasts 5 to 20 days, but in certain cases may be very prolonged, even up to 5 months (Lépine and Cruveilhier, 1935 *a*).

Pathology.

The majority of descriptions of the pathology refers to the landriform type of accident, as the other types only rarely prove fatal (see, e.g., Babès and Mironesco, 1908, Koritschoner and Schweinburg, 1925, Bassoe and Grinker, 1930, Getzowa, Stuart, and Krikorian, 1933, Stuart and Krikorian, 1933, Ch'en and Ch'eng, 1936).

General changes. It is somewhat difficult to give a systematic account of the pathology, as there is no change uniformly present in all cases. The following is a general account of the changes that frequently occur in the cord, the brain usually showing little beyond some edema and congestion.

The cord is soft, especially in the lower dorsal and lumbar areas, where the gray and white matters may be indistinguishable. Microscopically, there is much axis cylinder destruction, with considerable neuroglial proliferation. The vessels in the gray matter show perivascular cuffing with leukocytes and embryonal cells. Degeneration and satellitosis of the nerve cells may be seen. Negri bodies do not occur and the lesions are quite different from those of ordinary rabic infection. Demyelination occurs only rarely, as in Bassoe and Grinker's (1930) case, in which it was situated perivascularly.

Koritschoner and Schweinburg's (1925) cases. These authors studied 7 cases and observed a variety of pathological features. One case showed generalized hyperemia only, and another congestion and edema of the cord. The remaining 5 cases all showed evidences of myelitis, either hemorrhagic, disseminated, or transverse.

Marinesco and Draganesco's (1938) case. These authors described a fatal case of flaccid paraplegia with urinary retention. They found a necrotic myelitis, most evident from the 9th to 11th thoracic segments, in this area the majority of nerve cells was destroyed. Evidences of demyelination were found in the segments bordering on these areas. They also found lymphocytic infiltrations in certain peripheral nerves, nerve roots, and sympathetic ganglia.

Getzowa, Stuart, and Krikorian's (1933) cases. An interesting study of the pathological features of neuroparalytic accidents was made by these workers in Jerusalem, and is worthy of particular note. They studied the histopathology of 3 fatal cases of Landry's paralysis, 2 of these complicated antirabies treatment, but the other was spontaneous. All 3 cases were similar clinically and histologically.

any theory that attempts to account for the production of all cases of neuroparalytic accident.

(*a*) The accidents tend to be commoner with live or attenuated than killed vaccines.

(*b*) They have followed antirabies treatment in persons who have had no contact with the rabies virus at all (Remlinger, 1927 *b*, Getzowa, Stuart, and Krikorian, 1933, Ch'en and Ch'eng, 1936).

(*c*) They occur almost equally commonly in all classes of treated persons, whether bitten or not, and irrespective of their degree of risk by Hempt's classification (see p. 870).

(*d*) The onset of the illness bears no constant relationship to the date of the bite but rather to the date [illegible]

(*e*) In animals, paralysis may f [illegible] tissue.

(*f*) The pathological features [illegible], do not resemble those of rabies, and Negri bodies are not found

The main theories will now be discussed *seriatim*.

1. *Street virus theory*. This theory is really composed of two subgroups.

(*a*) *Modified rabies theory* That neuroparalytic accidents were caused by street virus was widely believed in the early days of Pasteur treatment (see, e g, Laveran, 1891) Any departures from the usual symptomatology of rabies were attributed to a modification induced by the treatment. The theory is scarcely held valid at the present day, thus at the time of the Rabies Conference only one institute spoke in its favor, it was, however, supported by Koch (1927). The main argument against this theory is that cases of neuroparalytic accident have been reported after exhibition of antirabies treatment in normal unbitten persons Further, the incubation period is too short, there is no hydrophobia, and the pathology of neuroparalytic accidents is not that of rabies.

(*b*) It has been suggested that neuroparalytic accidents may be caused by strains of street virus that show no cross immunity reactions with the ordinary vaccine strain of fixed virus That is to say, there is no reason why the antigen in the *virus fixe* vaccine should confer protection against an antigenically different street virus (Babès and Jonesco, 1924, Téodorasco, 1928). Because in this theory neuroparalytic accidents are held to be street virus infections, the same objections apply.

2 *Anaphylaxis theory* It has been thought that the development of neuroparalytic accidents may be due to an anaphylactic reaction occurring in the nerve tissues This theory was first put forward by Harvey and McKendrick (1907), who concluded that accidents were due to an excess of foreign nerve material, and suggested that this reacted anaphylactically That antigen-antibody [illegible], a part has more recently been suggested [illegible]

[illegible] acquired [illegible] it does prove possible to kill rab- [illegible] shock, this does not in any way resemble the ordinary neuroparalytic accident (Stuart and Krikorian, 1928). Next, human beings [illegible], a second or even further course of antirabies [illegible] show no special [illegible] and Bailly, 19 [illegible] had previously [illegible] courses of antirabies treatment in anima[illegible] any particular liability to [illegible]

3 *Ferment theory* Earlier [illegible]

cent., and at another institute (Weltewreden) 0.28 per cent. (see also Lubinski and Prausnitz, 1926, Remlinger, 1928 *a*, 1937 *b*).

(*c*) The killed phenolized vaccines (e.g., Semple's) have always been accepted as giving a low incidence of accidents However, such may occur (see, e.g., Cunningham and Malone, 1930, Tartakoff and Vibber, 1932; Stuart and Krikorian, 1928, 1930, 1933, Ch'en and Ch'eng, 1936, Béguet and Horrenberger, 1940, Piringer, 1942).

(*d*) Both the heated and killed ether vaccines give low figures, although cases of neuroparalytic accident do occur (for heated vaccine, see Babès and Jonesco, 1924, for etherized vaccine. Patrikios and Catacouzenos, 1933).

(*e*) The remaining methods (mixed and yatren) give a high incidence of neuroparalytic accidents

Rôle of dosage in the incidence of neuroparalytic accidents. Many workers have reported an increased number of neuroparalytic accidents following an increase in the quantity of nervous tissue injected. At the Rabies Conference, Boecker (see Remlinger, 1927 *b*) stated that very intensive treatment gave rise to 0.89 per cent. of accidents, intensive to 0.32 per cent, and mild to 0.19 per cent. Further, at the Conference, of 114 cases in which the intensity of treatment was noted, 57 occurred with intensive treatment, 39 with average, and only 18 with mild

The exact amount of injected nervous tissue is not the only factor in the production of neuroparalytic accidents, the state of the inoculum is of importance also Thus, according to Cornwall and Beer (1925–6 *a*), although 38 mg. of fresh cord per kilo body weight, or 18 mg of desiccated cord, may cause paralysis in man, 94 mg of carbolized tissue per kilo has never been responsible for a neuroparalytic accident.

In conclusion, it is evident that the methods involving the use of living or attenuated virus (e.g, cords, dilutions) give a high incidence of neuroparalytic accidents, while the killed vaccines (e.g, phenolized, etherized) give a low incidence

The etiology of neuroparalytic accidents.

A large number of theories has been propounded to account for these accidents of treatment, but there is no unanimity as to the correct explanation, and it is probable that it has not yet been discovered Certain facts must be explained by

of adult rabbit and monkey brain with added adjuvants (paraffin oil and dried tubercle bacilli). Usually 3 injections were given intramuscularly at weekly intervals. Symptoms usually developed after about 3–4 weeks, and took the form of ataxia, monoplegia, hemiplegia, quadriplegia, ocular paralysis, or tremor.

The pathological changes were those of acute disseminated encephalomyelitis Perivascular areas of inflammation and demyelination were found, the white matter was chiefly involved, but there was a secondary involvement of the gray matter. The inflammatory changes were more marked than those that occur in the demye- … e reactions with rabbit

… the injection of brain … n in the perivascular tissue, giving rise to inflammation and degeneration here and in the vessel wall. The fact that lesions were produced by homologous brain may be explicable by autoimmunization, and it would be necessary to postulate a liberation of brain tissue in an antigenic form. They quote a number of instances where antibodies have been detected in human blood to normal human tissues.

Morgan (1946, 1947) made essentially similar observations independently. Two to 7 weeks after 2–3 subcutaneous injections of poliomyelitis-infected monkey spinal cord plus adjuvants, the majority of monkeys showed signs of severe involvement of the CNS. The effect was reproduced by the injection of spinal cord or white matter of brain of normal monkey, and to a lesser extent by cortical gray matter, provided adjuvants were used Peripheral nerve and kidney suspension with adjuvant proved negative. It appeared that the responsible antigen was present in white matter, tentatively not in gray matter, and not in peripheral nerve. Perhaps the essential difference lay in the nature of the myelin of the cerebral white matter as contrasted to that of peripheral nerve. It was concluded that the reaction

…

of lesions in monkeys, following injections of normal brain tissue, which resemble those found in certain human cases of neuroparalytic accident.

6 *Neurotropic virus theory* Inasmuch as certain cases of neuroparalytic accident show a histological picture similar to that of true postvaccinal encephalitis and measles encephalitis, one must explore the possibility of a similar etiology. In postvaccinal encephalitis, as is well known, it has been postulated that vaccination "lights up" some neurotropic virus lying latent in the body (Ch XXXV), and it is possible that antirabies treatment may act in the same way However, the existence of such a virus has never been demonstrated with certainty. It has also been suggested that the vaccine itself may contain a neurotropic virus capable of causing neuroparalytic accidents

7 Virus fixe *theory* Some of those who support this theory believe that *virus fixe* is sufficiently pathogenic to account for all cases of neuroparalytic accident (e g, Fielder, 1916, Busson, 1929) That a few cases of death (*rage de laboratoire*) from infection with *virus fixe* have occurred is generally admitted, but the fact that neuroparalytic accidents may develop following treatment with killed carbolized vaccines would seem to render impossible the general acceptance of *virus fixe* as the etiological agent Further, in animals, neuroparalytic accidents have followed the exhibition of normal nervous tissue.

Another serious flaw in the acceptance of this theory is the fact that *virus fixe* has only been isolated from the brain of cases dying after antirabies treatment on a few occasions However, Remlinger (1935 *a*, 1937 *a*), doubtless representing an important section of modern French opinion, says that the belief is gaining ground that this failure to isolate virus is due to the presence of an autosterilizable neuro-infection That is to say, that *virus fixe* is initially present, but is destroyed by the

were found to occur about a week after the beginning of the course, and to persist for 2 to 3 weeks after its termination. The ferments gave Abderhalden's reaction with rabbit, human, and dog brain However, they were found in the serum of a person who developed a neuroparalytic accident as well as in the sera of others who remained well.

4. *Rabies toxin theory.* The theory that neuroparalytic accidents were due to the presence of a rabies toxin in the vaccine used to be widely held, and even at the Rabies Conference there were some supporters According to this view, the neuroparalytic accident is thought to be a toxic reaction, because of its sudden onset with pyrexia and its usually rapid recovery. However, if there were such a toxin one would certainly expect very many more cases than actually occur It is difficult to accept this theory, especially as a rabies toxin has never been convincingly demonstrated

5. *Constituent of normal nervous tissue theory.* That some constituent of normal nervous tissue might be the cause of neuroparalytic accidents was suggested many years ago (see Harvey and McKendrick, 1907). It was supported at the Rabies Conference, and is still accepted by many (see, e g, Schweinburg, 1930, Loeffler and Schweinburg, 1930). It is free from the objections that affect so many of the other theories, because if a person receives antirabies treatment at all he is bound to be injected with nerve tissue Whatever is the potent constituent of the nervous tissue it must be rendered less harmful by carbolic acid

The main proof of this theory has been attempted by experimental means

(*a*) Thus, rabbits have been subjected to injections of normal homologous or heterologous brain tissue (Remlinger, 1909 *a*, 1919 *f*, *g*, 1920 *a*, *b*, Schweinburg, 1924, Koritschoner and Schweinburg, 1925, Stuart and Krikorian, 1928). In many cases the animals have presented untoward symptoms, for some have died in convulsions after 4 to 5 injections, and others have developed paralysis

(*b*) Paralysis and wasting of the limbs, eventually proving fatal, may follow injections of carbolized nervous tissue (Harvey and Acton, 1922–3), Stuart and Krikorian (1928), however, obtained no untoward reaction after large doses of carbolized brain.

(*c*) Hurst (1932) investigated the effect of injecting normal, heated, and carbolized brain suspensions (guinea-pig, sheep, human, and monkey) into rabbits He found that many animals died, some suddenly, others with marked wasting Less than one-tenth of animals showed paralysis, and microscopically there were no definite lesions The evidence was insufficient, in Hurst's opinion, to state that neuroparalytic accidents were due to normal brain tissue.

(*d*) Schwentker and Rivers (1934) also injected rabbits with brain tissue. In a proportion of cases a complete paralysis of the hind legs developed Histologically, however, there were no specific lesions and certainly no demyelination They came to conclusions similar to Hurst's Certain more positive results have, however, been recorded with monkeys

(*e*) Rivers, Sprunt, and Berry (1933) gave repeated injections of brain extracts and emulsions to monkeys Following these injections some animals developed inflammatory changes in the central nervous system with demyelination.

(*f*) Rivers and Schwentker (1935) carried out a further series of experiments on monkeys The animals were given several intramuscular injections of aqueous emulsions and alcohol-ether extracts of sterile normal rabbit brains Histological changes were produced in which myelin destruction, mainly perivascular, was prominent

(*g*) Millischer (1938) found that the cerebral tissue of healthy animals elaborates, after death, a toxic substance capable of producing paralytic accidents in rabbits

(*h*) Important observations have been made by Kabat, Wolf, and Bezer (1946, 1947), who inoculated healthy young *M rhesus* monkeys with phenolized emulsions

cidents That there may be such a syndrome as this was clearly emphasized by Hempt at the Rabies Conference (see Remlinger, 1927 *b*). He reported 2 cases bitten by a healthy dog who were not even subjected to antirabies treatment. Some 4 and 8 weeks later both patients became paralyzed As Hempt points out, if these cases had been subjected to antirabies treatment they would naturally have been classed as cases of neuroparalytic accident.

cases of

occur-

cending

paralysis which developed 24 days after the beginning of the injections Street virus was isolated from the central nervous system This case was almost certainly an ordinary case of landriform rabies, with the antirabies treatment as an incidental and not the etiological factor. However, were it not for the isolation of street virus it might have been labelled as a Landry type of neuroparalytic accident.

These authors reported a somewhat similar

n confused with a neuroparalytic accident,

(*c*) *Marinesco and Draganesco's (1935) case.* This case has attracted much interest and will be described rather fully Clinically the case was a Landry's paralysis developing after antirabies treatment. To decide on the exact nature, a detailed histological examination was undertaken.

Over the cerebrum the meninges showed some hemorrhages, and cellular infiltration with polynuclears and mononuclears. The parenchymal changes were most pronounced in the frontal and ascending parietal area, there was some hyperemia and perivascular infiltration. Polymorphs were found, both perivascularly and diffusely; Babès nodules were present In the thalamus and gray matter underlying the ventricular ependyma there was a perivascular and diffuse infiltration of poly-

lesions gave place to degenerative changes Rabbits and guinea-pigs were injected with the central nervous system of this case, and a virus was isolated The animals became paralyzed on the 3rd day, and died after 5 to 6 days There was some doubt as to the precise nature of the virus, it was probably not a *virus fixe* strain, but resembled more *virus renforcé*.

This case was undoubtedly one of street virus infection with landriform symptoms Had pathological and biological tests not been carried out, it would probably have been regarded as a case of neuroparalytic accident

violent cellular reaction. Remlinger even suggests that *virus fixe* may be the etiological agent of the milder recoverable, as well as the severer fatal, cases. He would not attribute accidents following the use of killed vaccine to *virus fixe*.

Discussion.

Neuroparalytic accident is a most interesting condition. It must, however, be emphasized that the fact that it may occasionally occur must never be advanced as a contraindication to the administration of antirabies treatment to all exposed to the risk of rabies.

The condition is probably not unique in medicine, for it appears to be related to true postvaccinal encephalitis, and encephalomyelitis complicating smallpox, measles, influenza, and perhaps chickenpox, the fundamental feature of which diseases is the occurrence of perivascular demyelination. Considerable advance has been made in the study of the demyelinating diseases (see Ch. XXXV). It now appears certain that a number of viruses, as well as certain chemical agents and normal nervous tissue, can cause demyelination either by a direct effect on the myelinated tissue, or more probably by first producing a vascular thrombosis The difficulty arises, however, in that demyelination of this characteristic perivascular type has not frequently been found in cases of neuroparalytic accident complicating antirabies treatment. We are reluctant, therefore, to emphasize unduly the analogy between neuroparalytic accident and postvaccinal and other types of post-infective encephalomyelitis.

The views of Remlinger (1937 *a*), who has studied this problem for a lifetime, must always receive the most serious attention. He inclines to the view that there is no single cause of neuroparalytic accidents In some cases, especially where live virus is used, he blames *virus fixe* In other cases, mainly where killed vaccines are used, he believes that the etiological agent is probably the normal nervous tissue.

We would conclude by saying that it is most probable that all cases of neuroparalytic accident can be accounted for by supposing that either *virus fixe* or normal nervous tissue may be the etiological agent. Further, in view of recent findings in related disorders, it is likely that these agents exert their effects by producing intravascular thromboses in the central nervous system.

Differential Diagnosis of Paralysis after Antirabies Treatment

When paralytic symptoms develop in a person who has undergone a course of antirabies treatment, various possibilities must be considered.

1 *Paralytic rabies* The case may be one of paralytic rabies, unprevented by antirabies treatment The diagnostic features of such cases are usual incubation period of rabies, depending on the site of the bite, symptoms of paralysis are [illegible] fatal, histologi- [illegible] t virus from the

2. Rage de laboratoire The case may be one of *rage de laboratoire* with the following diagnostic criteria the incubation period may be longer than in neuroparalytic accidents, the disease usually beginning immediately after a course of injections, or up to 40 days later, the condition is fatal, and from the central nervous system *virus fixe* may be recovered

3 *Neuroparalytic accident.* The paralysis may be a true neuroparalytic accident, the diagnostic criteria being onset 13 to 15 days after the beginning of treatment, symptoms of Landry's paralysis, dorsolumbar myelitis or facial paralysis, no hydrophobia or excitement, a high recovery rate, in fatal cases, absence of lesions characteristic of rabies, including Negri bodies, and absence of street or fixed virus in the brain.

4. *Intercurrent paralysis.* The case may be one of intercurrent paralysis from some undetermined cause, these cases are, of course, notified as neuroparalytic ac-

CHAPTER LXXX

AUJESZKY'S DISEASE (PSEUDORABIES)[1]

PSEUDORABIES is a virus disease of the nervous system which affects a number of animals, such as cattle, horses, sheep, and pigs, under natural conditions. The infection was first described by Aujeszky in 1902, and occurs in many parts of Europe and the American continent. The disease goes by various names, for in addition to the two already mentioned, it may be called "mad itch." The term "pseudorabies" is misleading as the virus has no connection with that of rabies, and the diseases do not resemble each other in any important respect.

The virus is readily transmissible to rabbits and other experimental animals. Rabbits inoculated by various routes usually develop intense irritation of the skin and rapidly scratch or bite away the fur from the affected site. The disease is highly fatal, both naturally and experimentally. Experimental work has been carried out mainly by French and American authors, and much of this is reviewed in an article by Bosio (1938). Other reviews are those of Galloway (1938) and Remlinger and Bailly (1938).

PSEUDORABIES IN MAN

von Rátz (1913) reported that 2 boys had developed pruritus, after wounding

[illegible] These ob-

[illegible] disease was

[illegible] laboratory

[illegible]

subsided, but she complained of a headache, weakness, an urticarial rash on the feet, an aphthous eruption on the gums, and pain in the knees. Examination of the blood showed a hypercholesterolemia (240 mg. per 100 c c), and an eosinophilia (7 per cent).

Experimental observations. The blood serum of the 2nd case (removed at the height of the itching) was injected into 2 rabbits, 1 intracerebrally and the other subcutaneously. After 18 hours both showed the loss of hair so characteristic of infection with pseudorabies, the animals died from the infection. The loss of hair was most marked in the animal injected subcutaneously, all the hair had been scratched out around the site of inoculation. Blood was removed again, 8 days after the accident, but the virus was not recovered.

The histological features in the patient's brain and the first passage monkey were quite typical (Peers, 1940, 1941). The 4th monkey passage material was inoculated in eastern cotton rats, and produced paralytic symptoms The strain was also passed in mice, and has been very widely used in experimental work (Armstrong, 1939 *b*, 1941). The strain after a few passages in monkeys is pathogenic in these animals (Stefanopoulo and Vieuchange, 1946, Bodian and Cumberland, 1947). Monkeys are said to develop a fulminant infection on inoculation of the Lansing strain together with autolyzed mouse brain (Milzer and Byrd, 1947)

THE SK STRAIN

This strain was isolated from the feces of an abortive case on inoculation of monkeys by Trask, Vignec, and Paul (1938 *a*, *b*). Later, Jungeblut and Sanders (1940 *a*, *b*) succeeded in infecting cotton rats; it was then adapted to mice, and lost virulence for the monkey. After 70 transfers in mice, the strain showed an increased pathogenicity for monkeys and guinea-pigs (Jungeblut and Sanders, 1941; Jungeblut, Sanders, and Feiner, 1942).

A fixed strain of cavian passage virus has been developed by intracerebral passage in guinea-pigs

The SK strain, in its early monkey passages, was related antigenically to other strains isolated in the same epidemic, to the Aycock strain, and some 1934 Californian strains, it differed from certain other monkey-pathogenic strains (Trask, Paul, and Vignee, 1939). It was infective by the oral and intracutaneous routes in [illegible]

[illegible]

the Jungeblut SK strain may not actually be of human origin

THE MEF 1 STRAIN

This strain was isolated by van Rooyen in a rhesus monkey from a fatal case in a soldier in the Middle East campaign (Schlesinger, Morgan, and Olitsky, 1943). It infects cotton rats and mice.

OTHER RODENT-PATHOGENIC STRAINS

1. *Jungeblut and Dalldorf* (1943) isolated a virus causing paralysis of albino mice, cotton rats, and hamsters from the brain of a mouse found dead in the home of a fatal case of poliomyelitis. Another strain (MM) was isolated from the brain stem of this case, with a similar range of infectivity, although it was more potent for albino mice.

2 *Jungeblut and Dalldorf* (1946) isolated 2 strains (NY 65 and NY Pool II) from house mice in New York by intracerebral inoculation in albino Swiss mice. The strains were related but not identical, and were distinct from Theiler's and other murine strains

3 *Flexner's MV strain* was adapted to the cotton rat by Toomey, Frohring, and Takacs (1943).

4 *Toomey, Takacs, and Weaver* (1945) isolated in cotton rats a rodent-paralyzing virus from creek water

5 *The McG strain* is a weak strain of rodent-paralyzing virus (see Dalldorf and Whitney, 1943).

6 *Milzer and Byrd* (1947) report that human strains can be adapted to mice, hamsters, and cotton rats by suspension of the material in a 10 per cent. suspension of autolyzed mouse brain They were able to adapt a monkey-passed strain (Leon) to mice and cotton rats They also claim to have isolated several strains from human cord and feces by this technique in mice.

SECTION 9. THE POLIOMYELITIS GROUP

CHAPTER LXXXI

THE POLIOMYELITIS GROUP OF VIRUSES

UNTIL a few years ago it was believed that poliomyelitis virus caused infection of man alone. Experimentally, it was thought to be transmissible only to the monkey or chimpanzee. It is now known that certain human strains can be transmitted to cotton rats, mice, and other rodents. Further, a number of agents has been discovered that is closely related in biological properties to the human virus, and causes natural infections in swine, mice, and other rodents.

As an introduction to the study of human poliomyelitis and a full understanding of its essential biological characteristics, it is essential to be familiar with the modern conception of "the poliomyelitis group of viruses." For example, Gard (1943 *a*)[1] has proposed the use of the terms human, murine or mouse, and porcine or swine, types of poliomyelitis virus. In addition, certain other terms are in general use. Monkey-adapted strains are known as monkey or simian strains. Strains causing paralysis in rodents, irrespective of their source of origin, are known as rodent strains. At the moment, the criteria for classification in this group are not clear, and we include provisionally certain strains that may later be shown not to be true members of the group.

The main members of the poliomyelitis group of viruses are as follows

MONKEY-PATHOGENIC STRAINS OF HUMAN ORIGIN

The bulk of strains isolated from human cases of poliomyelitis is transmissible to the monkey and chimpanzee, and cannot be adapted to rodents After establishment in monkeys, such strains are referred to as monkey-pathogenic or simian strains It is accepted that such strains have derived from the human material, for there is no definite evidence that monkeys are ever spontaneously infected with viruses of the poliomyelitis group The term "ordinary strain" also refers to a monkey-pathogenic strain. The best known of these strains are as follows MA (Flexner and Lewis, 1909 *a*), K (Flexner and Lewis, 1909 *a*, *b*), LP (see Levaditi and Hornus, 1932), Rockefeller mixed or MV, Aycock or Ay (Aycock and Kagan, 1927), New York 1931 strain (see Flexner, 1932), Wfd (Trask and Paul, 1936, 1938, German and Trask, 1938); Sacramento (Howitt, 1937 *a*), McK (Kessel, Stimpert, and Fisk, 1938), Peiping No. 1 (Yen and Hsu, 1941), Mar, isolated in Australia in 1937 and used by Burnet and collaborators

RODENT PATHOGENIC STRAINS OF PRESUMED HUMAN ORIGIN

A number of strains has been isolated with the property of causing infection in rodents The circumstances have been such as to render it more likely that these strains derived from the human material used to initiate the transfers, than from the rodents employed for inoculation.

THE LANSING STRAIN OF ARMSTRONG

This strain was isolated in monkeys by Armstrong (1939 *a*) from the brain and cord of an 18-year-old boy who died of bulbar poliomyelitis in Lansing, Michigan

[1] References are appended at the conclusion of Ch LXXXVIII, p. 1026 et seq

The histological features in the patient's brain and the first passage monkey were quite typical (Peers, 1940, 1941). The 4th monkey passage material was inoculated in eastern cotton rats, and produced paralytic symptoms. The strain was also passed in mice, and has been very widely used in experimental work (Armstrong, 1939 *b*, 1941). The strain after a few passages in monkeys is pathogenic in these animals (Stefanopoulo and Vieuchange, 1946, Bodian and Cumberland, 1947) Monkeys are said to develop a fulminant infection on inoculation of the Lansing strain together with autolyzed mouse brain (Milzer and Byrd, 1947).

THE SK STRAIN

This strain was isolated from the feces of an abortive case on inoculation of monkeys by Trask, Vignec, and Paul (1938 *a*, *b*). Later, Jungeblut and Sanders (1940 *a*, *b*) succeeded in infecting cotton rats, it was then adapted to mice, and lost virulence for the monkey After 70 transfers in mice, the strain showed an in- [illegible] nd guinea-pigs (Jungeblut and Sanders, 1941; [illegible] irus has been developed by intracerebral passage in guinea-pigs

The SK strain, in its early monkey passages, was related antigenically to other strains isolated in the same epidemic, to the Aycock strain, and some 1934 Californian strains, it differed from certain other monkey-pathogenic strains (Trask, Paul, and Vignec, 1939) It was infective by the oral and intracutaneous routes in monkeys at this time (Vignec, Paul, and Trask, 1939). In the Yale laboratory, the original strain, now known as Y-SK has also been found pathogenic for cotton rats and mice, but after this adaptation differs in many properties from Jungeblut and Sanders' SK strain (Melnick and Horstmann, 1947). It is possible, therefore, that the Jungeblut SK strain may not actually be of human origin

THE MEF 1 STRAIN

This strain was isolated by van Rooyen in a rhesus monkey from a fatal case in a soldier in the Middle East campaign (Schlesinger, Morgan, and Olitsky, 1943) It infects cotton rats and mice.

OTHER RODENT-PATHOGENIC STRAINS

1. *Jungeblut and Dalldorf* (1943) isolated a virus causing paralysis of albino [illegible] for albino mice

2. *Jungeblut and Dalldorf* (1946) isolated 2 strains (NY 65 and NY Pool II) from house mice in New York by intracerebral inoculation in albino Swiss mice. The strains were related but not identical, and were distinct from Theiler's and other murine strains.

3. *Flexner's MV strain* was adapted to the cotton rat by Toomey, Frohring, and Takacs (1943).

4 *Toomey, Takacs, and Weaver* (1945) isolated in cotton rats a rodent-paralyzing virus from creek water.

5 *The McG strain* is a weak strain of rodent-paralyzing virus (see Dalldorf and Whitney, 1943)

6 *Milzer and Byrd* (1947) report that human strains can be adapted to mice, hamsters, and cotton rats by suspension of the material in a 10 per cent. suspension of autolyzed mouse brain They were able to adapt a monkey-passed strain (Leon) *to mice and cotton rats*. They also claim to have isolated several *strains from* human cord and feces by this technique in mice.

CHAPTER LXXXI

THE POLIOMYELITIS GROUP OF VIRUSES

UNTIL a few years ago it was believed that poliomyelitis virus caused infection of man alone. Experimentally, it was thought to be transmissible only to the monkey or chimpanzee It is now known that certain human strains can be transmitted to cotton rats, mice, and other rodents Further, a number of agents has been discovered that is closely related in biological properties to the human virus, and causes natural infections in swine, mice, and other rodents.

As an introduction to the study of human poliomyelitis and a full understanding of its essential biological characteristics, it is essential to be familiar with the modern conception of "the poliomyelitis group of viruses" For example, Gard (1943 *a*) [1] has proposed the use of the terms human, murine or mouse, and porcine or swine, types of poliomyelitis virus. In addition, certain other terms are in general use. Monkey-adapted strains are known as monkey or simian strains Strains causing paralysis in rodents, irrespective of their source of origin, are known as rodent strains. At the moment, the criteria for classification in this group are not clear, and we include provisionally certain strains that may later be shown not to be true members of the group

The main members of the poliomyelitis group of viruses are as follows.

MONKEY-PATHOGENIC STRAINS OF HUMAN ORIGIN

The bulk of strains isolated from human cases of poliomyelitis is transmissible to the monkey and chimpanzee, and cannot be adapted to rodents After establishment in monkeys, such strains are referred to as monkey-pathogenic or simian strains It is accepted that such strains have derived from the human material, for there is no definite evidence that monkeys are ever spontaneously infected with viruses of the poliomyelitis group The term "ordinary strain" also refers to a monkey-pathogenic strain. The best known of these strains are as follows MA (Flexner and Lewis, 1909 *a*), K (Flexner and Lewis, 1909 *a, b*), LP (see Levaditi and Hornus, 1932), Rockefeller mixed or MV, Aycock or Ay (Aycock and Kagan, 1927), New York 1931 strain (see Flexner, 1932), Wfd (Trask and Paul, 1936, 1938, German and Trask, 1938), Sacramento (Howitt, 1937 *a*), McK (Kessel, Stimpert, and Fisk, 1938), Peiping No. 1 (Yen and Hsu, 1941), Mar, isolated in Australia in 1937 and used by Burnet and collaborators.

RODENT PATHOGENIC STRAINS OF PRESUMED HUMAN ORIGIN

A number of strains has been isolated with the property of causing infection in rodents. The circumstances have been such as to render it more *likely that these* strains derived from the human material used to initiate the transfers, than from the rodents employed for inoculation

THE LANSING STRAIN OF ARMSTRONG

This strain was isolated in monkeys by Armstrong (1939 *a*) from the brain and cord of an 18-year-old boy who died of bulbar poliomyelitis in Lansing, Michigan

[1] References are appended at the conclusion of Ch LXXXVIII, p 1026 et seq

horn cells In addition, there are inflammatory changes consisting of perivascular and focal infiltration with round and glial cells. The nature and distribution of the lesions are very similar to that in mice infected with the Lansing strain

Distribution of virus.

In animals spontaneously paralyzed, virus is present in the brain and cord. In carriers, virus is present in the intestinal tract, to a lesser extent in the intestinal wall, and mesenteric glands, but not in the viscera or CNS (Olitsky, 1939, 1940 *c*). Virus occurs mainly in the upper part of the small intestine; the viral activity of the intestinal contents exceeds that of the intestinal wall by about ten-fold, it is suggested that multiplication may occur in intestinal organisms (Gard, 1945). On recovery from paralysis, the virus may persist in the cord for a year (Theiler, 1937).

Experimental infection in other animals.

Theiler's virus is not pathogenic to *monkeys* by intracerebral injection (Theiler, 1937, Olitsky, 1940 *b*).

Jungeblut (1943) passed the GD VII strain intracerebrally in *cotton rats*. The virus increased in virulence for these animals and mice, and produced nervous involvement in guinea-pigs and monkeys

Strains of virus

The n:
and GD
togenic th

Titration of infectivity.

Gard (1940 *b*, 1943 *a*) has studied the problem of the titration of infectivity in considerable detail, and has introduced an "incubation time" method for use with the strains FA and GD VII He also studied the 50 per cent. end point titration method, and found that the relation of this titer to the actual virus concentration was dependent not only on the resistance of the cells of the test animal to invasion, but on the physical state of the virus particles The incubation time method was largely independent of the latter condition, and gave more reliable information about the virus content He found that one MID as a rule comprised more than one active virus particle.

The interference phenomenon.

Gard (1944) found that brain suspensions from mice surviving an attack induced by a strain of low virulence, protected against infection when injected intracerebrally together with a more active strain (see p. 916 for more details).

Morphology

Estimates of the particle diameter by filtration are 13–19 mμ (Theiler, 1937), or 9–13 mμ

THEILER'S ENCEPHALOMYELITIS OF MICE

The disease was first noted by Theiler (1934, 1937) in the mouse stock at the Rockefeller Institute, New York. He found that certain members of the stock were spontaneously paralyzed, and showed evidence of encephalomyelitis A virus was isolated from the CNS of these animals by intracerebral injection in apparently normal mice.

The infection has many points of resemblance to poliomyelitis in man and is of considerable interest, particularly from the point of view of epidemiology and ecology (see Theiler, 1941; Gard, 1943 *a*).

Clinical features.

The spontaneous disease affects young mice, aged 4-8 weeks, who show flaccid paralysis, commonly of the hind limbs. The incidence of paralytic disease in infected mouse stocks is very low, probably under 1 per 1000, although almost all the members may be intestinal carriers (see below).

Epidemiology.

The disease has been reported not only in North America, but in South America (Roca-Garciá, 1944), Germany (Gildemeister and Ahlfeld, 1938), Japan (Iguchi, 1939), and Sweden, Palestine, and Uganda (see Gard, 1943 *a*).

The infection was originally described in albino mice, but Olitsky and Schlesinger *(1941 b) found intestinal carriers among a number of wild gray mice caught in the* neighborhood of infected albino mice.

Gahagan and Stevenson (1941) isolated from normal mouse stocks a virus closely resembling, but apparently not identical with, that of Theiler.

The virus is widely distributed in members of infected stocks. It is excreted in the feces, and the infection is spread from animal to animal by this means (Olitsky, 1939). *Suckling mice do not show virus in the feces, but it first appears at about 20 days of age;* by 2 months the majority of animals is infected, young mice harbor more virus than older animals (Olitsky, 1940 *a;* Theiler and Gard, 1940 *b*).

The virus has also been detected in the intestines of kangaroo rats *(Dipodomys merriami)* housed near albino mice carrying the virus (Melnick, 1943 *b*)

Experimental infection in mice.

Mice are infected most readily by the intracerebral route, but can also be infected nasally, by injection into the tongue, or intraperitoneally (Theiler, 1934, 1937, Theiler and Gard, 1940 *a;* Olitsky and Schlesinger, 1941 *a;* Young and Cumberland, 1943) Flaccid paralysis develops after an incubation period of 7-30 days.

Jungeblut (1944 *b*) found that rapid passage through mice endowed the strain with an enhanced power of invading the CNS from the periphery.

Young mice are more susceptible than older animals Animals under 4 weeks of age may die without developing paralysis Older animals may suffer from an inapparent *infection On recovery, a residual paralysis of the hind legs may follow*

Mice fed a diet deficient in thiamine showed a lower incidence of infection than controls; in some cases, when deficient animals were later given adequate thiamine they became paralyzed (Rasmussen *et al*, 1944). A less marked decrease in susceptibility was [illegible] in calories Deficiency of riboflavin had no effect [illegible] and Lichstein, 1944) [illegible] y in calcium pantothenate exhibited a definitely [illegible] 1944). Deficiencies in pyridoxine, inositol, and biotin had no consistent effects on the susceptibility of mice (Lichstein *et al*, 1945)

Histology.

The histological features of the natural and experimental disease are similar (Theiler, 1934, 1937, 1941, Olitsky, 1939, Olitsky and Schlesinger, 1941 *a, c*)

The most characteristic lesion is necrosis of the ganglionic cells in the anterior horn Intranuclear inclusions may be seen in the early stages Isolated ganglion cells in the cerebrum and midbrain may also be attacked Neuronophagia is not such a pronounced feature as in the *human being or monkey, and the infection seems to spare more anterior*

TABLE 37[1]

COMPARISON BETWEEN THE VIRUSES OF HUMAN AND MOUSE POLIOMYELITIS AND THE TESCHEN DISEASE (FROM GARD, 1943 *a*)

	Human Poliomyelitis	*Mouse Encephalomyelitis*	*Teschen Disease*
Clinical picture	Preparalytic stage of fever and meningeal symptoms	Not known	Fever and meningeal symptoms
	Paralytic stage: flaccid paralysis, mainly of the limbs	The same	The same
	The ascending type of paralysis common	The same	The same
	Cerebral forms exist, with ataxia and spastic symptoms	Cerebral forms exist, tonic-clonic convulsions main symptoms	Cerebral forms common in young animals, spastic symptoms
	Nonparalytic forms exist	The same	The same
	Incubation period of experimental disease, usually 10–14 days	The same	The same
Pathology	No gross lesions	The same	The same
	Histological lesions confined to the CNS	The same	The same
	Primary process: neuronal disintegration, neuronophagia	The same	The same
	Secondary features: glial reaction, round cell infiltration, perivascular cuffing	The same	The same
	Principal site of lesions anterior horns of the spinal cord	The same	The same
Epidemiology	Annual morbidity rate about 1:10,000 Epidemic attack rate sometimes up to 10 p c	Attack rate about 1 5,000	Epizootic attack rate up to 50 p c
	Age distribution prevalence of children and young adults	Prevalence of young mice	Prevalence of young animals
	In temperate climates characteristic seasonal distribution	Seasonal distribution even	Cold-wet seasons preferred
	Portal of entry of virus not definitely known, probably alimentary tract, principally intestine	Not known, probably intestine	Not known
	Elimination of virus principally feces	The same	Not known
	True contact cases probably rare	The same	The same
Immunology	Reinfections are very rare	Solid immunity after recovery from spontaneous or experimental infection	The same
	Immunologically different strains of virus seem to exist	The same	Not known
	Neutralizing substances appear in the blood with age, apparently no connection with clinical disease	The same	Not known
	Attempts at precipitin reaction and complement fixation unsuccessful	The same	Not made

Concentration and purification.

Suspensions diluted beyond the infectivity point can be concentrated by pervaporation (Melnick, 1942).

Gard, using a method of purification involving ether, 40 per cent saturation with ammonium sulfate, ultrafiltration, and fractional ultracentrifugation, has isolated a protein material from infected mouse brain which seems to represent the actual virus (Gard and Pedersen, 1941; Gard, 1943 *a*). This work is fully described on p 1004.

He has isolated from the stools of normal white mice a substance he calls "intestinal protein" When isolated from young animals, this substance is infective, but a similar material from older animals is not.

Some other properties of the virus.

In nerve tissue, virus is markedly reduced in infectivity in 30 minutes at 45° C, and milk exerts a protective effect for 5-10° C degrees extra, in intestinal content, virus is completely destroyed at 55° C., irrespective of the suspending fluid (Lawson and Melnick, 1947).

The virus survives for at least 150 days in 50 per cent. glycerol (Theiler, 1937). It is precipitated by ammonium sulfate, and has an optimum pH stability at pH8 or 33 (Theiler and Gard, 1940 *a*). Trask, Melnick, and Wenner (1945) calculated the amounts of chloramine and hypochlorite needed to lower appreciably the infective titer. Brain homogenates show a marked inhibition of glucose phosphorylation (Racker and Krimsky, 1947).

Theiler's virus can be recovered from adult *Musca domestica* 12 days after infection by feeding (Bang and Glaser, 1943).

Immunity.

On recovery from a spontaneous or experimental paralytic or inapparent attack, animals are resistant to inoculation (Theiler, 1937, Olitsky, 1939). Intraperitoneal or intranasal administration of virus gives rise to active immunity, as does the intracerebral injection of an avirulent strain (Theiler and Gard, 1940 *a*) Active immunity is also acquired by healthy carriage of the virus in the gut, probably because some virus is absorbed and reaches the lymph glands

Suckling mice show antibodies in their sera, presumably these antibodies are derived from the mother, as they disappear by 3 weeks, in older animals, virus neutralizing antibodies have again appeared (Olitsky, 1940 *b*, Theiler, 1941). Casals and Palacios (1941) described a complement fixation reaction between antisera and infected brain tissue Human sera only rarely neutralize virus (Seligmann and Jungeblut, 1943, Olitsky and Findlay, 1946)

Relationship to other members of the poliomyelitis group

The antigenic relationship of Theiler's virus to other members of the poliomyelitis group is fully discussed below

Gard (1943 *a*) concludes that mouse encephalomyelitis and human poliomyelitis are closely related In his opinion there are no essentially distinguishing features between the two, except the species specificity The two viruses should be regarded as variants or types of the same species, until evidence to the contrary is produced Table 37 from Gard's (1943 *a*) paper presents the main features of the 2 diseases along with those of the Teschen disease of swine (see below)

THE TESCHEN DISEASE

Gard (1943 *a*) gives the following description The Teschen disease of pigs or *Encephalomyelitis enzootica suum* was first recognized in Czechoslovakia in 1929, but is now more widespread in Europe Certain forms of the disease are characterized by flaccid paralysis Histologically, there is loss of ganglion cells, and mesodermal-glial reaction in the anterior horn cells and base of the brain The disease can be transmitted to young swine by intracerebral injection There is no doubt that the disease has certain points of resemblance to human poliomyelitis and Theiler's disease, although there are differences (see Frauchiger and Hofmann, 1941).

(Jungeblut, 1944 *a*; Dalldorf and Whitney, 1945, Melnick and Horstmann, 1947). In all probability, certain murine strains share antigenic components with simian strains (Jungeblut, 1944 *a*, Milze and Byrd, 1947). Thus, Toomey and Takacs (1941 *c*) found the Lansing strain to be neutralized by convalescent antiserum in the same manner as were monkey strains (see also Harford and Bronfenbrenner, 1941). Experiments with hyperimmune monkey serum indicated a relationship between the McK and MV monkey strains and the Lansing strain (Kessel, Moore, and Pait, 1946). Jungeblut, Sanders, and Feiner (1942) showed that SK was neutralized by antiserum prepared in the horse to a monkey strain, however, antiserum to the murine strain did not inactivate the monkey strain. They concluded that SK and other murine strains should be regarded as variants of the monkey-pathogenic type of virus.

As regards Theiler's virus, it appears to be antigenically distinct from monkey strains, as shown by Theiler (1937). Olitsky (1940 *b*) found that Theiler's virus was not inactivated by antiserum from convalescent human beings or monkeys; *vice versa*, serum from mice convalescent from infection with Theiler's virus did not neutralize monkey virus. There does not seem to be any relationship between Theiler's virus and the Lansing strain (Young and Cumberland, 1943; Levaditi and Vaisman, 1945).

Dalldorf and Whitney (1945) using cross neutralization and cross immunity tests, found no relationship between MM virus and Theiler's original TO strain, complement fixation, however, showed a relationship between the strain GD VII of Theiler and the MM virus

Jungeblut, Sanders, and Feiner (1942) found that Theiler's virus was neutralized by antiserum to the murine SK strain, and to a lesser extent by antiserum to a monkey strain. However, mice recovered from infection with Theiler's virus were fully susceptible to infection with SK Later, Jungeblut (1943) in cross neutralization tests, could not demonstrate any relationship between Theiler's virus and the SK strain Melnick (1943 *b*) came to the same conclusion using complement fixation tests The Y-SK strain is not related to Theiler's virus (Melnick and Horstmann, 1947) Mice immunized against the monkey strain Leon adapted to mice were not resistant to inoculation with the FA strain of Theiler's virus (Milzer and Byrd, 1947)

We may conclude that all the viruses referred to show some antigenic relationship, and 3 broad groups can be defined (1) monkey-pathogenic strains; (2) Lansing, SK, MM, and probably certain other strains, (3) Theiler's virus In group 2, the relationships one to another are probably closer than to groups 1 or 3. The relationship between groups 1 and 2 is probably closer than between 1 and 3 or 2 and 3

ANTIGENIC RELATIONSHIP OF THE POLIOMYELITIS GROUP TO OTHER VIRUSES

Vaccinia Infection with neurovaccinia did not modify the characteristic lesions of poliomyelitis, and vaccinia did not "activate" a weakly active strain of poliomyelitis (Hurst and Fairbrother, 1931) Poliomyelitis is not neutralized by vaccinial antiserum (Jungeblut, 1934)

Foot-and-mouth disease No cross immunity was found between the neurotropic strain and Theiler's virus (Levaditi and Vaisman, 1945).

antirabic sera (Jungeblut, 1934).

neutralized by antiherpetic sera

Lymphocytic choriomeningitis. There is no evidence of a serological relationship between the SK strain and the virus of LCM (Jungeblut, Sanders, and Feiner, 1942, Sanders and Jungeblut, 1942).

COMPARISON BETWEEN THE VIRUSES OF HUMAN AND MOUSE POLIOMYELITIS AND THE TESCHEN DISEASE (FROM GARD, 1943 *a*)—*Continued*

	Human Poliomyelitis	*Mouse Encephalomyelitis*	*Teschen Disease*
Distribution of virus	In clinically manifest cases: virus in the CNS but no other tissues except the intestinal wall and sometimes mesenteric lymph nodes	The same	Virus in the CNS, intestines with contents not examined
	Healthy carriers harbor virus in the intestines, to what extent not known	Carrier state is the rule	Not known
Properties of the virus	Infectious spectrum narrow: man, certain primates, occasionally cotton rat and mouse	Infectious spectrum narrow: albinotic mouse, gray mouse, occasionally cotton rat	Ordinary laboratory animals refractory
	Under experimental conditions strictly neurotropic	The same	The same
	Generally not cultivable in tissue culture	The same	No attempts
	Filtration end-point 30 mμ	Filtration end-point: 30 mμ	Not studied
	Remarkable resistance in vitro	The same	Not studied

ANTIGENIC RELATIONSHIPS IN THE POLIOMYELITIS GROUP

Antigenic Structure of Monkey-Pathogenic Strains

Flexner (1932) drew attention to antigenic differences between human (i.e., freshly isolated) and monkey-passed strains, passage through monkeys modified antigenic structure so that antisera detected quantitative and qualitative differences, monkey virus still induced active immunity to human virus Paul and Trask (1933), however, found that animals recovered from infection by a human strain were not protected against passage virus, and vice versa. Human convalescent sera showed a qualitative difference in neutralizing power against human and passage strains

Other workers, using cross neutralization tests, have noted degrees of antigenic differences between human and passage strains (e.g., Burnet and Macnamara, 1929, 1931; Weyer, 1931-2, Southby and McKie, 1933, Erber and Pettit, 1934, Kessel *et al*, 1936-7, Howitt, 1937 *a;* Burnet and Keogh, 1938, Kessel, Stimpert, and Fisk, 1938). Thus, Burnet and Macnamara found that monkeys recovered from infection with their Australian strain succumbed to the MV strain Howitt reported that antiserum prepared in monkeys to the Sacramento strain did not protect against passage material, while certain animals immune to Sacramento virus succumbed to passage virus. It is evident, therefore, that antigenic differences can be detected between human and monkey-passed strains

Freshly isolated strains can also vary one from another Thus, Trask *et al* (1937 *a*, *b*) found that immunological differences existed between human strains isolated in various outbreaks in 1931 and 1934 (see also Stimpert and Kessel, 1939) Trask, Paul, and Vignec (1939) also detected differences between human strains Kessel, Moore, and Pait (1946) found antigenic differences between strains, unrelated to the number of passages.

ANTIGENIC STRUCTURE OF MURINE STRAINS AND RELATIONSHIP TO SIMIAN STRAINS

Neutralization and cross immunity tests have shown that the SK, Y-SK, MM, and Lansing strains are related, and probably share common antigenic components

He found that if mice survived infection with a strain of low virulence, they became immune, and their brain suspension would protect other mice against infection, if injected intracerebrally along with active virus. A less pronounced protective effect was demonstrated when brain was given intraperitoneally. The protective power was not dependent on the virus content, and was attributed to the presence of a specific inhibitor. This inhibitor was attached to the tissue component of the suspension, and was not soluble in water or saline. It did not combine with virus *in vitro* It appeared with the onset of symptoms.

Canine distemper. Rhesus monkeys infected with distemper virus are immune to poliomyelitis, but this resistance disappears in convalescence (Dalldorf *et al.*, 1938).

Epidemic keratoconjunctivitis. No relationship was found between Theiler's virus and the agent of this disease (Sanders and Alexander, 1943).

Roca-García's viruses. The 3 viruses isolated by Roca-García (1944) did not immunize mice definitely against Theiler's virus.

OTHER BIOLOGICAL RELATIONSHIPS OF THE POLIOMYELITIS GROUP

Simultaneous Infection with Poliomyelitis and Other Viruses

Lymphogranuloma. When mice infected with LGI were injected with poliomyelitis virus, the lesions characteristic of LGI developed as usual, when the two viruses were mixed *in vitro* prior to inoculation in mice, the lesions of LGI developed, but when inoculated in monkeys those of poliomyelitis were noted (Vieuchange, 1936 *c*).

Rabies. Rabies virus and the Lansing strain can be passed together intracerebrally for several passages, because rabies attacks the brain and poliomyelitis the cord (Levaditi, 1943).

The Interference Phenomenon

The interference phenomenon was first demonstrated in poliomyelitis by Dalldorf (1939), who noted that the virus of lymphocytic choriomeningitis had a "sparing" effect on experimental poliomyelitis in the monkey; this effect was reciprocal to a lesser degree Later it was found that hamsters injected intracerebrally with LCM virus failed to develop symptoms on intraperitoneal injection of the MM strain (Dalldorf and Whitney, 1943), a similar interfering effect was produced by the rodent paralyzing strains McG, Lansing, and SK.

Jungeblut and Sanders (1940 *a*) showed that interference occurred on simultaneous intracerebral inoculation in the monkey of the murine SK strain and the original monkey SK strain; interference also occurred if either was given 48 hours before the other.

The murine SK strain, in the form of a suspension of mouse brain, was found to interfere with the propagation of the Aycock and RMV monkey strains in rhesus monkeys (Jungeblut and Sanders, 1942). The mixture could be prepared *in vitro*, or the two agents could be injected separately, by different routes. Interference did not occur with heated infected brain, normal brain, or herpes-infected brain. If murine virus was inoculated intravenously in monkeys, before or after an intracerebral injection, a distinct interfering effect was observed It was suggested that a blockade of susceptible cells by the nonparalyzing murine virus rendered these cells insusceptible to invasion by the monkey-paralyzing virus.

Tissue-cultured SK virus also showed the interfering effect in monkeys (Sanders and Jungeblut, 1942).

The cavian passage strain of SK, when injected intravenously, did not act as an interfering agent against an intracerebral injection of the monkey RMV strain (Jungeblut, Feiner, and Sanders, 1942)

Jungeblut (1945) further investigated the interference phenomenon in rhesus monkeys, and found that phenolization and formolization rendered the SK strain "noninterfering." Preparations subjected to UVL retained some interfering properties. He was unable to separate the interfering property from infectivity. He also found that the MM strain interfered with the development of monkey strains. Theiler's virus, on the other hand, did not prevent infection due to monkey strains

The interfering agent in the SK or MM strains may be the virus particle itself, as has been shown in the case of influenza On the other hand, the work of Gard (1944) with Theiler's virus suggests that this may not be the correct explanation

ber of excellent articles, reviews, and smaller books of a general nature has also appeared (e g., Flexner, 1912, 1915, Peabody, Draper, and Dochez, 1912; Kling and Levaditi, 1913 *a*, *b*, Draper, 1917, 1935, Amoss, 1928, 1930, Schultz, 1932; Faber, 1933, 1941; *League of Nations Epidemiological Report*, 1935, Brodie, 1938, Perdrau, 1938, Camps, 1940, Toomey, 1940 *b*, 1941 *a*, *b*, 1943 *b*, Bashford, 1941; Paul, 1941; Trask and Paul, 1941 *a*, Bedson, 1943; Brooks, 1943, Fraser, 1943, Gautier and Bamatter, 1943, Wyllie, 1943, Selby, 1945, Sabin, 1947, Nelson, 1947). Fishbein, Hektoen, and Salmonsen (1946) have compiled a very extensive bibliography covering the years 1789–1944, several thousand papers are mentioned, short summaries being given in many cases.

FACTORS PREDISPOSING TO POLIOMYELITIS

As will become evident, it is now known that the virus of poliomyelitis is widely distributed in epidemic periods, especially in the intestinal tract of close contacts. As only a minority of such infected persons appears to develop symptoms, it is important to inquire whether there is any evidence that certain factors may predispose to the development of clinical poliomyelitis.

Physique. Draper (1917, 1932, 1935) has maintained that children suffering from poliomyelitis regularly display certain morphological characteristics. The children are usually large and plump. The face is broad, and in about half the cases the upper central incisors are definitely separated, frequently other teeth stand free also. In older persons, on the contrary, the teeth are often crowded, and maxillary prognathism occurs The subcostal angle may be narrow, and the hand short and broad The pelvis may be wide in relation to the shoulder girdle, males may show poor development of the genitalia.

A very characteristic feature is the shape of the palpebral fissure, the inner half of the upper lid curving downward, and the inner canthus being lower than the outer. The eye is definitely "slit" in appearance and gives a mongoloid look to the face. Pigmented moles or freckles are commonly found on the face, neck, and upper part of the chest. The skin is smooth and hairless.

The whole condition of the patient suggests some widespread endocrine disturbance. Distinctive properties have been found in the leukocytes, grown in tissue culture (Draper, Ramsey, and Dupertuis, 1944). In view of Draper's wide experi-

may play a part in predisposing to attack (Addair and Snyder, 1942, Aycock, 1942 *a*) Armstrong and Davis (1945) found no evidence that paralytic attacks were more frequent in the children of parents who did not readily produce virus

ttee, 1932)

ce of paralysis may be due to

is inclined to occur in (

predispose to the dise

vitamin C predisposes to infection and severity of attack. Hypoglycemia may be a factor in determining susceptibility (Sandler, 1941).

Trauma There is a fairly general impression that overexertion or other more specific injury predisposes to infection (see, e g, Lovett and Lucas, 1908, Batten, 1910, Wayson, 1918 *a*, Leake, 1936 *a*, Muller, 1941).

Parker (1937) reported 3 cases where following a fall, or a blow to a limb, poliomyelitis developed with the main incidence in the traumatized limb Martin

CHAPTER LXXXII

ACUTE ANTERIOR POLIOMYELITIS (INFANTILE PARALYSIS)

Historical

PALEOPATHOLOGY shows that poliomyelitis existed in ancient Egypt. During the course of archaeological excavations south of Cairo, Flinders Petrie (International Committee, 1932) unearthed a skeleton (dating from about 3700 B C.), the left leg of which was much shorter than the right, probably caused by the disease. Other

nasty

iphis

, the

foot of which is shown lying in the typical equinus position.

A number of cases of paralysis associated with muscular wasting was recorded in the 18th and 19th centuries both in the British Isles and elsewhere, of which those recorded in England by Badham (1836)[1] should be specially mentioned. In a paper entitled "Four Remarkable Cases of Suddenly Induced Paralysis in the Extremities" he described illnesses in young children which were very suggestive of poliomyelitis as we now know it. In certain cases there were some preparalytic disturbances, but in others paralysis was the first manifestation. Badham was of the opinion that this was a disease *sui generis* and unrelated to other conditions known in his day. His paper was instrumental in stimulating Heine to publish a book on the subj[illegible] of the

disease.

quently

ment of

limbs.

Cases were recorded by a number of other workers after interest had been aroused by Heine's writings. Medin (1891, see also 1896) recorded the features of a large Swedish outbreak, and first convincingly showed that the attack of the pathogenic agent was not limited to the cord only, but that the higher centers might be involved In recognition of their pioneer work the disease is often referred to as the Heine-Medin disease.

Epidemics of the disease became extremely prevalent from the end of the 19th century onward, and many theories were current regarding the etiology, that it was an infective condition was suggested by Wickman's work on the epidemiology (1907). This view was proved to be correct by Landsteiner and Popper (1908, 1909) who succeeded in infecting a monkey with human material. It soon became evident, largely by the researches of Flexner and his colleagues in America, that the pathogenic agent was a filtrable, uncultivable virus.

Since the beginning of this century our knowledge of the virus agent has increased greatly, but there are still aspects of the epidemiology and immunology of poliomyelitis that await elucidation

The disease has always attracted the greatest interest in the literature, and we have estimated that well over 10,000 papers have been published In the face of such a mass of literature, it is obviously impossible to mention any save the most important contributions to our knowledge. The standard reference work on poliomyelitis is the *Report of the International Committee* (1932), and those desiring fuller information on any point should consult this most complete volume A num-

[1] References are appended at the conclusion of Ch LXXXVIII, p 1026 et seq

liminary stage of general infection. Many now hold that the earlier manifestations of infection are due to the presence of ... 'she, 1933). Others have postulated a prelimi... by subarachnoid and meningeal invasion (...

CLASSIFICATIONS

Wickman (1907, 1913) recognized the following varieties spinal, landriform,

lower motor neuron paralyses

The classification of the International Committee (1932) is as follows (1) Abortive type with no constitutional symptoms and no evidence of CNS involvement. (2) Nonparalytic type with transient weakness probably due to edema of ...cortical paralysis, ...) Cerebral or en-... (5) Ataxic type, probably due to involvement of the cerebellum, Clarke's column, and the intervertebral ganglia

Another classification is that of Faber (1933), and suggested earlier by Peabody, Draper, and Dochez (1912) and Draper (1917). The disease is divided into 4 phases the first 2 occur early and late in the preparalytic stage, the 3rd phase is that of paralysis, while the 4th phase is that of recovery

Powell (1938) recognized ... febrile phase without paraly... paralysis in the second, (5) ... (6) an acute febrile illness without paralysis.

Adamson and Dubo (1942) describe 3 types characterized by. (1) no paralysis or changes in the CSF, but typical clinically; (2) no paralysis, pleocytosis present, clinically typical, (3) paralysis present

The International Committee differentiates between 2 types of preparalytic poliomyelitis, the abortive type occurring early, and the nonparalytic type occurring later More recently it seems that the terms "abortive" and "nonparalytic" have become synonymous

ILLNESS OF INFECTION

There may be a transient minor illness within a day or so of the presumptive date of infection, characterized by nasopharyngitis, fever, and headache (International Committee, 1932, Abegg, 1942, Fanconi and Zellweger, 1942, Conybeare, 1946, McFarlan, 1946, McFarlan, Dick, and Seddon, 1946).

It is probable that persons may show these symptoms at the time of exposure to infection, without necessar...

After 1 to 2 days of syr... patient recovers and appears ... may supervene It has been ... illness (see below) can be explained on the basis of the first febrile "hump" being an illness of infection, and the second "hump" denoting the end of the incubation period, and the beginning of invasion (Paul, see International Committee, 1932, McFarlan).

The illness of infection is usually caused by the poliomyelitis virus itself, but in some cases as mentioned above may be due to other infectious agents

NONPARALYTIC (ABORTIVE) CASES

An increasing interest has been taken in these cases of recent years, for in any epidemic there are likely to be several times as many nonparalytic as paralytic

(1933) has described cases of poliomyelitis following on a simple fracture (see also Zenke, 1939).

Exposure to extremes of temperature, wetting, and operations may act as predisposing factors (see Muller, 1941; Keller, 1942). Salt-depletion and hemoconcentration have been blamed by Rinehart (1944). Faradic stimulation in the incubation period was not found to influence the site of initial paralysis but it caused a severer lesion (Swan, 1941).

Infections. Some authors suggest that poliomyelitis often supervenes on another infection such as measles, chickenpox, whooping cough, bronchitis, enteritis, or sore throat (International Committee, 1932; Muller, 1941; Zeller, 1942; Zellweger, 1945) There may be some relationship between susceptibility to diphtheria and poliomyelitis (Heaslip, 1938 *b*).

Tonsillectomy. There has been a large number of cases reported where bulbar or bulbospinal poliomyelitis has developed within 7 to 30 days of tonsillectomy or adenoidectomy (Aycock and Luther, 1929, Ayer, 1929, Brown, 1931–2, Fischer and Stillerman, 1937, Anderson and Dixon, 1938, Eley and Flake, 1938, Kramer, Gilliam, and Molner, 1939, Fischer, Stillerman and Marks, 1941, Helms, 1941 *a*, Aycock, 1942 *b*, Toomey and Krill, 1942, Zellweger, 1943, Howard, 1944, Page, 1944,

Bahlke, 1947).

In these cases either virus is present in the throat at the time of the operation, or else it is deposited there later, while the tissues are still traumatized Virus presumably ascends to the bulb via nerves exposed at the operation. A tragic instance of this condition has been recorded where tonsillectomy was performed on 5 apparently healthy children, who all contracted bulbar poliomyelitis (Krill and Toomey, 1941, Francis *et al.*, 1942. It is probable that tonsillectomy or adenoidectomy may predispose the patient to infection even weeks later (Aycock, 1942 *b*, Lucchesi and LaBoccetta, 1944)

It is possible that peripheral trauma may cause changes in the brain or cord around the central connections of the nerves supplying the affected area, if virus is already present in the CNS, it may be activated by such changes (Horstmann and Paul, 1947)

The onset of these cases is sudden, with sore throat, cough, and pyrexial disturbance There are paralytic phenomena such as strabismus and ptosis, facial paralysis, and dysphagia, trismus is also present The main histological changes occur in the bulb.

Pregnancy There is little doubt that pregnancy predisposes to poliomyelitis, and that there is a higher incidence in pregnant women than in a control group otherwise comparable (McGoogan, 1932, Aycock, 1941, 1946, Helms, 1941 *a*, Harmon and Hoyne, 1943, Blair and Robertson, 1944, Dhunér, 1944, Fox and Sennett, 1945, Horstmann, Ipsen, and Lassen, 1946, Fox and Waisman, 1947). The fetus is not affected by the disease.

INCUBATION PERIOD

The incubation period is 7 to 10 days In the 1941 epidemic in Alabama, Casey (1942 *a*) studied 37 cases developing following the visit of a prior victim, the incubations varied from 5–35 days, with an average of $12 \cdot 2 \pm 1 \cdot 1$ days

CLINICAL FEATURES AND COURSE OF THE DISEASE

The conception of poliomyelitis has changed greatly in recent years For one thing, nonparalytic cases are now recognized to be very much commoner than frankly paralytic ones For another, Hurst's work on the pathogenesis (see below) of experimental poliomyelitis has caused many to abandon the older view of a pre-

The above description is that of the most commonly observed features of preparalytic cases, without particular reference to time. According to Faber (1933) the clinical features can be described in two phases from the point of view of time.

Features of Phase 1. Here, the symptoms are thought to be due to involvement of the brain stem and basal nuclei. The earliest symptoms are those either of drowsiness and listlessness or of restlessness and irritability. Fever is usually present. There are frequently psychic disturbances in which the sleep rhythm may be inverted, and the child hyperesthetic. Gastro-intestinal disturbances, vomiting, anorexia, and constipation are common. A number of signs such as flushing, quick pulse, and irregular action of the heart may be noted. There is no loss or clouding of consciousness, the cerebrum being relatively unaffected by the virus. It is suggested that these various disturbances of the first phase are most readily explicable by their having a subcortical origin in the thalamus (e g., hyperesthesia) or hypothalamus (e g, sleep, fever, disturbances of the vasomotor system). Even at this early stage, there may be changes in the cerebrospinal fluid (see below). Some cases may not develop any further, but many progress to Phase 2.

Features of Phase 2. The thalamic and hypothalamic disturbances of Phase 1 persist, but as the virus spreads nearer to the cord, sensory symptoms develop, due to involvement of the posterior columns This phase is sometimes known as "posterior poliomyelitis." The neck is now stiff and rigid, and there is muscular ataxia and tremor, while the reflexes may be increased. Pains may be spontaneous, or produced by touching and handling the child It is suggested that this phase is due to an involvement of the posterior columns and root ganglia, and not to meningeal irritation

The majority of preparalytic cases runs through both these phases of illness, but does not progress any further. Phase 1 may merge gradually into Phase 2, or they may be separated by a distinct interval, and when this is so they are known as "dromedary" cases, from the two humps of reaction separated by a more or less normal period. The average length of the preparalytic period is about 4 days.

Dromedary cases were originally described by Draper in 1917 and have been noted by other authors (e.g, Macnamara, 1928; Macnamara and Morgan, 1932; Gard, 1937; Hunt, 1938, McAlpine, 1945, 1946). They appear to be commoner in some outbreaks than others. The duration is variable, being often as much as 14 days Thus for 2 to 3 days the patient is drowsy, febrile, may vomit, and may have an upper respiratory catarrh. Thereafter improvement sets in for up to 7 days, to be succeeded by 1 to 2 days of definitely nervous involvement, with neck rigidity, the "spine sign," pains, tenderness, and other features as described above.

The dromedary, or biphasic type of illness has been said to be of bad prognostic [illegible]

common at the beginning than the end of an epidemic (5 per cent. as against 60 per cent of all cases), and suggested that the shorter the time between the two phases the severer the attack.

There are at least 2 interpretations for the dromedary case (see Horstmann and Paul, 1947). Either the incubation period is the interval between exposure and the first hump, or the interval between the two humps, the first being in the nature of an illness of infection.

[illegible]

tha [illegible]

sec [illegible]

other infections, and appropriate laboratory tests may have to be employed to make the distinction Lymphocytic choriomeningitis and "serous meningitis" (Brodie,

cases. In an outbreak in New Haven in 1931, Paul, Salinger, and Trask (*1933 b*) found that 5 to 8 per cent. of children under 10 years old (of a selected group) had frank paralytic poliomyelitis, while 30 to 40 per cent. had nonparalytic poliomyelitis. Abortive cases are commonest below 16 years of age (Paul, Salinger, and Trask, *1933 b*).

The diagnosis in the preparalytic stage presents a difficult problem especially in nonepidemic periods. The clinical features have been described frequently since the days of Wickman (1907), (e.g., Muller, 1910, Peabody, Draper, and Dochez, 1912; Frost, 1913, Draper, 1917, Zingher, 1917 *b*; Macnamara, 1928, Kramer and Aycock, 1931–2; Gordon, 1932, Paul, Salinger, and Trask, 1932, *1933 a, b*, Macnamara and Morgan, 1932; Trask and Paul, 1933; Faber, 1933; Martin, 1933, Walshe, 1933, Baastrup, 1935; Siegl, 1936, Bingold, 1936; MacNalty, 1936, Muller, 1936; Nissen, 1936, Gard, 1937; Lucchesi, 1937, Stender, *1937*, Wieland, *1937*, Aguirre, 1938; Gsell, 1938, Holst, 1938, Stahel, 1938, Hamilton, 1940, Adamson and Dubo, 1942, Agius *et al.*, 1945, Debono, 1945; McAlpine, 1945, 1946).

Preparalytic poliomyelitis begins in various ways. Fever is usually present for 1 to 4 days. "Influenzal" and catarrhal symptoms are common, with sore throat, tonsillitis, and nasopharyngitis. Frontal headache is frequent. In another group, the onset is with gastro-intestinal symptoms of diarrhea, vomiting, and abdominal pain. Convulsions may occur. In the Malta (1942–43) outbreak there was no obvious relation between the mode of onset, and the distribution of the subsequent paralysis (Agius *et al*, 1945).

Pain in the head, neck, back, and limbs is common, and is due to a generalized hyperesthesia; it is elicited when any attempt involving movement, especially of the spine, is made (see Debono, 1945). The location of the pain does not usually correspond to the site of subsequent paralysis, and the severity has no relation to the *extent of paralysis (Agius et al., 1945)*.

Stiffness in the neck and back and resistance to anterior flexion are very common. If the child is lying down and the head is gently raised, pain is usually complained of, and rigidity is experienced by the observer. *If the shoulders are* raised, the head usually falls back to the bed. Another test is to sit the child on one's knee and then tempt him with toys. On reaching out he will try to bend his neck forward, and experience pain (Macnamara, 1928). Older children, when asked to bend forward to kiss their knees, will be unable to do so. Another well-known sign is Amoss's or the tripod sign. The child is asked to sit straight up in bed, when he will be found to place his hands on the bed behind himself, for support. The child's arms and trunk thus resemble a tripod in shape (see Hannah, 1937) Kernig's sign is often weakly positive. Muscular tremors often occur, and usually herald the site of forthcoming paralysis The skin may be hyperesthetic, and show vasomotor disturbances, such as flushings and sweatings. Gard (1937) has stressed the importance of a cyanotic tinge of the face with circumoral pallor. The abdominal reflexes are often lost, and the tendon jerks unequal.

The child is usually irritable, restless, and often snarling. Apathy and stupor *may occur in some cases* Gard (*1937*) *found a number of cases* with encephalitic symptoms of somnolence, delirium, ataxia, nystagmus, clonus, and spasms Although many of these progressed to develop definite flaccid paralyses, others did not, and had to be *considered as cases of nonparalytic poliomyelitis* (see also Agius *et al.*) Adamson and Dubo (1942) stress the diagnostic value of the triad of symptoms of spontaneous pain in the head and back, stiffness of the neck and back, and fever

Nonparalytic cases *should be kept in hospital for at least 4 weeks*, as paralysis may develop later (Gard).

Examination of the cerebrospinal fluid is of the very first importance Cases can scarcely be accepted as preparalytic poliomyelitis *unless the cell count is at least* 12 per c mm. The count frequently reaches higher figures, even occasionally 1,000 cells per c.mm (see below).

upper part of the digestive system. He finds that these bulbar cases fall into 5 *groups of increasing grades of severity*.

1. The clinical manifestations are those of a facial paralysis It is suggested that the virus spreads by the chorda tympani to the nucleus salivatorius (adajacent to the 7th nucleus).
2. Both 6th and 7th nerves are paralyzed owing to the proximity of their nuclei It is suggested that the virus spreads from the facial nucleus to involve the abducens nucleus.
3. Other nuclei neighboring the 7th are involved, with more widespread symptoms of bulbar paralysis
4. [illegible] ...ract as well as the facial nucleus, and
5. [illegible] intestines simultaneously, giving rise ... 7th nucleus.

The Minnesota Poliomyelitis Research Commission (1947) studied nearly 200 cases in 1946, and suggested the following classification: (1) bulbar-cranial nerve nuclei group, (2) bulbar-respiratory center group, (3) bulbar-circulatory center group, (4) bulbar-encephalitic group, (5) combined bulbar-cervical cord group

The landriform type of poliomyelitis *may be confused with other forms of* Landry's paralysis The disease may begin in the hip muscles and spread rapidly in both directions, or it may begin in the arms and spread to the neck and down to the legs

The cerebellar type is associated with pronounced ataxia, nystagmus, and incoordination *(see Neal, Du Bois, and Abrahamson, 1916–19, Glanzmann, 1937)* *Meningitic* and *polyneuritic* types are also described

The sympathetic nervous system in poliomyelitis The paralyzed limbs may show vasomotor disturbances, being cyanotic and cold Toomey (1931–2 *c*) found that the superficial abdominal reflexes were lost or diminished before paralysis appeared, and *suggested that this might be due to sympathetic paralysis* He injected paralyzed patients with atropine, histamine, and adrenalin without definite results When pilocarpine was injected, sweating began sooner, and lasted longer, on the skin of the paralyzed limb than the normal (see also Toomey, 1934 *b*) When epinephrine was injected into these patients, sweating ceased at once over the normal limb, *whereas it was unaffected over the paralyzed limb* Twenty-one days after the onset the paralyzed side reacted normally. These results are certainly suggestive [illegible]

[illegible]

later (Phase 2), the abdominal [illegible] changes in the knee jerks, and lastly (Phase 3), the abdominal reflexes and knee jerks are both diminished or lost.

The sense of smell Hyland *et al.* (1938) did not find any abnormality.

Differential diagnosis Numerous cases diagnosed as the Guillain-Barré syndrome of acute infectious polyneuritis have probably been suffering from poliomyelitis (see De Sanctis and Green, 1942, Jones, Holmes, and Weinstein, 1943, Jervis and Strasburger, 1943, Blumberg, Mahoney, and Wenger, 1944, Brazier *et al*, 1944, Nicholson, 1946) Certain neurological infections of undetermined etiology may *mimic poliomyelitis (see Babonneix, 1939–40)*.

THE STAGE OF RECOVERY

A remarkable feature of the disease is that persons profoundly paralyzed, even in all limbs, may recover completely in a matter of a few weeks. Recovery begins

1937; Lassen, 1939); simple infections of the upper respiratory tract (Levin *et al*, 1942); sandfly, dengue, and dengue-like fevers (Bernstein, Clark, and Tunbridge, 1945; Paul, Antes, and Sahs, 1945). Many cases diagnosed as "meningismus" may in reality be abortive poliomyelitis (Illingworth, 1945). In N. America there is some difficulty in making a clinical diagnosis between equine encephalitis, St. Louis encephalitis, mumps meningitis, and abortive poliomyelitis

PARALYTIC CASES

The commonest types of paralytic poliomyelitis are the ordinary or spinal, the polioencephalitic, and the bulbar or bulbospinal types, but certain others are described.

Spinal type. If carefully questioned, the great majority of cases will be found to have shown some evidences of infection in the preparalytic stage. In other cases, [illegible] ikes up with a limb paralyzed. [illegible] after a lapse of about 7 days, [illegible] volved are those of the lower extremity, especially the anterior tibial and other groups below the knee. In severer cases, the muscles of the pelvic girdle may be affected, making it impossible for the child to flex the hip joint. The abdominal and intercostal muscles may be involved, as may the diaphragm, and in such cases the outlook is very serious, death usually occurring from respiratory paralysis When the arms are paralyzed, this is usually more marked in the proximal than in the distal groups. Nelson (1946) found that there was a significant predominance of paralysis in the left, as compared with the right, arm. Paralysis of the neck muscles is often associated with respiratory paralysis, and is of very bad prognostic import. The characteristic changes in the reflexes and in the cerebrospinal fluid are described separately. Localized pain may occur, sometimes associated with muscular spasm Pain and tenderness may be found in nonparalyzed as well as paralyzed muscles, because the inflammation of the sensory neurons does not necessarily occur at the same level as the changes involving the anterior horn cells (see Moldaver, 1944). By means of the pathesthesiometer it has been shown that sensory changes occur, in the nature of a lowered threshold of vibratory sensibility (Frohring *et al*, 1945) Nelson (1946) draws attention to disturbed circulation in the involved extremities

Polioencephalitic type Despite suggestions to the contrary (see Martin, 1933) there is no doubt that the virus can cause a true encephalitis The neurological signs differ from those commonly observed in spinal poliomyelitis, in that convulsions and other cerebral manifestations occur

The bulbar type of poliomyelitis is associated with cranial nerve paralysis The facial nerve is most commonly affected, the abducens and other ocular nerves are more rarely involved This type of illness usually carries a high mortality rate, and may be associated with paralysis of the limbs and trunk. Cranial nerve paralysis has been noted more commonly in some outbreaks than others (Ruhrah, 1917, Bull, 1937–38, Sherman, 1944, Nicholson, 1946).

In the Malta 1942–43 outbreak, 11 per cent of native cases showed only a facial paralysis (Agius *et al*, 1945), while 28 per cent of service cases showed cranial nerve palsy (Bernstein, Clark, and Tunbridge, 1945) Wyllie (1944) has described a small family outbreak, 1 person developing paralytic poliomyelitis, and 2 persons Bell's palsy Stebbins, Gillick, and Ingraham (1939) described an outbreak of 20 cases, 13 of whom showed bulbar symptoms, only 2 had had a tonsillectomy, 12 died In the 1946 Minneapolis epidemic, Pohl (1947) found that a complaint of sore throat was 10 times more frequent in cases in which bulbar features eventually developed than in those which later showed paralysis of spinal origin

Some bulbar cases may develop after tonsillectomy (see above) Toomey (1936 *a*) has made a study of bulbar cases, and has suggested that virus reaches the bulb by the chorda tympani fibers in the facial nerve, that is to say, from the

MORTALITY

Death is almost invariably due to paralysis of the diaphragm, often with a terminal respiratory complication such as pneumonia. The great bulk of deaths occurs in the first week of illness with a few in the second, and scarcely any thereafter. The case fatality rate varies rather widely from epidemic to epidemic and locality to locality; an average figure is 20 per cent, with outside limits of 5 to 50 per cent. The rate is considerably higher in the case of children under one year and in elderly persons.

During the Second World War, British service personnel often suffered a high mortality rate in poliomyelitis outbreaks, for example, in Malta 11/57 men died (Bernstein, Clark, and Tunbridge, 1945), and in India the mortality rate rose to 37 per cent (McAlpine, 1945); a similar experience befell other troops

The mortality in bulbar cases varies from 60 to 80 per cent.

CLINICAL PATHOLOGY

The cerebrospinal fluid. Examination of the cerebrospinal fluid is of great diagnostic importance, particularly in the preparalytic stage Numerous authors have published the results of their examinations, in which there is almost complete unanimity (e g., Gay and Lucas, 1910, Draper and Peabody, 1912; Peabody, Draper, and Dochez, 1912; Fraser, 1913, Neal and Jones, 1916–19, Neal and Kahn, 1916–19, Zingher, 1917 *b*; Kolmer *et al*, 1917; Gordon, 1932; Drury and Sladden, 1939, Bernstein, Clark, and Tunbridge, 1945).

The changes begin in the preparalytic stage, and continue for a variable part of the paralytic period. The fluid is usually under slightly increased pressure, and hazy, after standing for some hours, a fibrin clot may form.

Increase in the cell count is one of the first manifestations of infection, beginning in the preparalytic stage, the greatest number of cells is to be found in the first week after the onset of paralysis. The count usually remains raised for 3 weeks after the onset of paralysis, and thereafter declines The total number of cells is seldc [illegible]
per ([illegible]

[illegible]

is more common in nonparalytic cases

The total protein becomes increased also but, unlike the cell count, is greater in the 3rd week than the 1st. The protein may become normal after 10 to 13 days, only to rise later (Bernstein, Clark, and Tunbridge, 1945). Some increase may still be present after 7 weeks. The colloidal gold curve is of the luetic or meningitic type, while the colloidal benzoin test is frequently positive (Kessel, Hoyt, and [illegible]

with or without complement, may be present (Kolmer *et al*, 1917). Spolverini (1946) found an increase in the ascorbic acid content.

It may be necessary to examine more than 1 sample, especially if the 1st is examined toward the end of the 2nd week, when the cell count may have fallen to normal, and the protein increase hardly have begun (Eyre-Brook, 1942).

Rehm (1939) examined cell deposits by histological methods, and found small acidophil granules in the nuclei of lymphocytes, which enlarged to form inclusions

It is not possible to relate clinical severity to the cell count or protein content.

The blood and urine Changes in the blood are not of such importance as those in the cerebrospinal fluid, but have been extensively studied by certain authors

usually after about a week, and by 4 to 6 weeks should be well advanced. It is generally believed that muscles still paralyzed after 6 months will never recover their function. Probably about one-third of all cases show some permanent paralysis and atrophy occurs with the production of characteristic deformities.

Some psychic disturbances may be found after convalescence, such as nervousness, anxiety, affections of sleep, and mental change (see Faber, 1933).

Persons who have suffered from poliomyelitis in early life are not more liable than others to contract encephalitis lethargica (Klimke, 1937).

THE KENNY CONCEPTION OF POLIOMYELITIS

Miss Kenny has advanced a very different conception of poliomyelitis from the orthodox one already outlined. In the orthodox view, damage to the anterior horn cell is the main factor, and produces flaccid paralysis of the muscle fibers innervated therefrom. Opposing muscles may contract and shorten, but are not recognized to be otherwise abnormal. A primary attack of virus on muscle has not been visualized. Miss Kenny's views of recent years have been published in various American sources (e.g., Kenny, 1943, 1943–4, 1944; Pohl and Kenny, 1943). Her theories appear to be as follows

1. Muscle spasm is present in every case of poliomyelitis, paralytic, and nonparalytic. The spasm is found in the muscles directly affected by the disease, and causes them to be painful and hyperirritable. This muscle spasm is made up of 2 phenomena, both resulting from hyperactivity and hyperirritability of the synaptic connections to the motor nerve cells in the cord, hypertonus of muscles, and the hyperirritable stretch reflex. Spasm is the primary lesion Although initiated in the CNS, it seems to be due to a direct effect on the muscle also.

2. The flaccid muscles are usually intrinsically sound, and can be restored to normal function by treatment The inability to contract these "paralyzed" muscles is due to "mental alienation" from the nervous system. A physiological "block" in the motor pathway is postulated, so that nervous impulses do not reach the anterior horn cells These nonfunctioning muscles can be contracted only on releasing spasm in its opponents, and on restoring the physiological continuity of the nerve conduction paths.

3 Incoordination of muscle action appears in the untreated case It is often found in a single muscle, and can be observed in reflex as well as voluntary motion. It is fundamentally a disorganization of muscle function on an involuntary level.

4 Paralysis due to destruction of the nerve cell is not nearly as common as is imagined Most supposed paralysis is due to untreated spasm and to disease in the dissociated muscle

5. Deformities resulting from orthodox methods of treatment are due to untreated muscle spasm

Miss Kenny's claim is that disturbance of physiological function of the nervous system is of more importance than structural damage to the nerve cells The disease is held to affect muscles directly as well as nerve cells Based on her theories, a system of treatment has been introduced, but it is not in our province to discuss the technique (see Pohl and Kenny, 1943)

According to Schwartz and Bouman (1942), spasm is a reflex phenomenon, and, therefore, absent in a completely paralyzed muscle Spasm is explicable in terms of a lesion at, or proximal to, the dendrite or cell body of the lower motor neuron, which partially isolates the lower neuron from the inhibition exerted by higher levels, spasticity and weakening are 2 separate phenomena, each dependent on disturbed functions of the anterior horn cells (Schwartz, Bouman, and Smith, 1944)

Kabat and Knapp (1944) state that spasm is of 2 types, either hypertonus, or due to the hyperirritable stretch reflex They suggest that spasm is the result of an increased discharge of impulses through the motor neurons, and claim that the pathological basis of spasm is a lesion of the internuncial neurons in the gray matter of the cord Chronaxia estimations showed that there is no correlation between spasm and damage to the anterior horn cells Other workers have referred to the question of spasm (Cole, Pohl, and Knapp, 1942, Fox and Spankus, 1945, Brainerd *et al*, 1945)

Paul (1938) recommends concentration of washings by freezing and drying in the presence of normal serum

Horstmann, Melnick, and Wenner (1946) recommend the following technique The throat swab is soaked in 10 per cent sterile horse serum in distilled water, and the throat rubbed vigorously. The patient then gargles on several occasions 50–75 c.c. of 10 per cent horse serum In young children a nasopharyngeal irrigation with 10 per cent horse serum can be used instead of gargling The swab material and garglings are then available for concentration by centrifugation or other means, prior to inoculation in monkeys

Howe and his coworkers employ 2 swabs, after use, the cotton portions are stored in 1 c c of sterile water on dry ice, and at a convenient time treated as follows (Howe *et al*, 1944, Howe, Bodian, and Wenner, 1945, Wenner, 1945) elution is performed in phosphate buffer at pH8, the cotton being squeezed out, the eluate is corrected to pH6, 20 per cent ether is added, and the fluid kept in the refrigerator till sterile, the ether is removed, and the fluid inoculated into both lateral thalami of a monkey

Washings may be collected by a mechanical irrigator (Atlas, 1947) Virus has been recovered from a mask (Ward and Walters, 1947)

Occurrence of virus. Virus has been recovered from nasopharyngeal washings on a number of occasions from preparalytic and from early spinal or bulbar paralytic cases (Du Bois, Neal, and Zingher, 1914, Amoss and Taylor, 1917; Flexner and Amoss, 1919, Paul, Salinger, and Trask, 1932, Paul and Trask, 1932, Paul, Trask, and Webster, 1935, Kramer *et al*, 1936, Stillerman and Brodie, 1937–8, Trask, Vignec, and Paul, 1938 *b*, Vignec, Paul, and Trask, 1938, Kramer, Hoskwith, and Grossman, 1939, Howe, Bodian, and Wenner, 1945, Melnick, Horstmann, and Ward, 1946, Howe and Bodian, 1947).

Nasal secretions and saliva usually fail to yield virus (Sabin, 1941 *b*), although Lucas and Osgood (1913) and Ward and Walters (1947) have isolated it from nasal secretion

tic cases (Du Bois, Neal, and Zingher, 1914; Amoss and Taylor, 1917, Flexner and Amoss, 1919). Sabin and Ward (1941 *d*) found virus in the pharyngeal wall but not in the nasal mucosa or salivary glands

It has been recovered also from tonsils and adenoids (Landsteiner, Levaditi, and Pastia, 1911 *b*, Flexner and Clark, 1911, Levaditi, Schmutz, and Willemin, 1930, Brodie, 1934–5 *d*, Kessel *et al*, 1941) In these cases of course, it is not possible to exclude contamination with pharyngeal secretion

The tracheal secretion of fatal cases may contain the virus (Kling, Wernstedt, and Pettersson, 1911–12)

Duration of infectivity Virus may persist in the nasopharynx for over 2 weeks from the time of onset of the preparalytic phase (Du Bois, Neal, and Zingher,

prove nega-
Horstmann,
on the 7th
carriage in

found may depend to a certain extent on the presence of virucidal properties in normal nasopharyngeal secretions (Amoss and Taylor, 1917). The active principle is water-soluble and thermolabile, and its potency may be diminished or lost in inflammatory states of the upper respiratory passages

Comparative examinations of stool and nasopharynx As will be described below, virus is constantly to be found in the stools of preparalytic and paralytic cases All the evidence suggests that virus is present for a very much longer time in the feces than in the throat For example, of 19 tests on pharyngeal swabs taken during the first week of illness, only 1 was found positive, of 16 tests on oropharyngeal washings, only 1 was positive, but of 10 inoculations of stools in the same period 7 were positive (Horstmann, Melnick, and Wenner, 1946).

(e.g., Gay and Lucas, 1910; Draper and Peabody, 1912; Peabody, Draper, and Dochez, 1912). From a study of these and other reports it appears that the commonest finding is of a leukocytosis up to about 25,000 per c.mm., in the paralytic stage. The differential count usually shows an approximate 10 to 15 per cent. increase of polynuclears with a relative lymphopenia. The sedimentation rate is usually normal (Fox and Evrard, 1946). A considerably increased excretion of coproporphyrin III in the urine was noted in a series of cases of acute poliomyelitis (Watson *et al.*, 1947).

Routine bacteriological examination. Examinations of the nose and throat, urine, and stools have never shown any significant abnormality; this observation has been reaffirmed by Toomey (1935 *a*). Convalescent sera are said to show an increase in *B. coli* and paratyphoid bacillus agglutinins (Toomey, 1931–2 *b*, 1934 *a*).

DISTRIBUTION OF VIRUS IN PREPARALYTIC AND PARALYTIC CASES

Virus must be constantly present in paralytic cases in the spinal cord, and probably also to a lesser extent in the base of the brain and in the higher centers. Although accurate titrations of virus have not been performed, it is probable that the quantity of virus in the cord, or bulb in bulbar cases, is considerably greater than in the brain. Virus cannot be demonstrated in the cord of every fatal case, perhaps for purely technical reasons, and it is easier to detect it in younger persons. Thus 71 per cent. of cords from patients under 16 years of age were positive, as compared with 31 per cent. from persons of 16 years and over (Kessel *et al.*, 1941).

The virus was rarely detected in the olfactory bulbs (Kessel *et al.*, 1941), and Sabin and Ward (1941 *d*) obtained negative results. It has been found in the intervertebral ganglia (Flexner, Clark, and Amoss, 1914 *b*), and abdominal sympathetic plexus (Sabin and Ward, 1941 *d*).

Most workers have failed to isolate virus from the cerebrospinal fluid in the preparalytic or paralytic stages (e.g., Leiner and Wiesner, 1909, Flexner and Clark, 1914, Amoss, 1928, Brodie and Wortis, 1934). Positive results have been claimed by Ceccaldi (1943).

It is not known whether virus is actually present in the central nervous system in the preparalytic period, but this appears highly likely, from comparison with monkey experiments (see Bodian, 1946, 1947).

Blood, Urine, Lymph Glands

Virus has not usually been detected in the blood (Flexner and Clark, 1911, Clark, Fraser, and Amoss, 1914, Amoss, 1928, Melnick, Horstmann, and Ward, 1946). Out of approximately 100 samples from patients suffering from abortive or paralytic attacks, a positive result was obtained in only 1 child, 6 hours after the onset of an abortive attack (Ward, Horstmann, and Melnick, 1946).

Virus has not been found in the urine (Sabin, 1941 *b*, Toomey, Tischer, and Takacs, 1943).

Virus has on a few occasions been isolated from mesenteric, inguinal, axillary, and cervical lymph nodes (Flexner and Lewis, 1910 *d*, Kling, 1937, 1938 *b*, Kling, Olin, and Gard, 1938, Wenner and Paul, 1947).

Investigation of a number of extraneural tissues proved negative (Kempf and Soule, 1940 *a*). It may be concluded that the thoracic and abdominal viscera only rarely contain virus.

Upper Respiratory Passages

Technique. Virus may be sought in throat washings or garglings, or in material removed by cotton wool swabs. Suspensions of tonsils can be examined, or of pharyngeal or nasal mucous membranes in fatal cases.

suspension separated into the lower aqueous fraction, the surface ether layer, and an intermediate layer of particulate "insoluble" material.

bacteriological examination The extract remained in the cold room until tests showed *that it was free from viable bacteria.* On removal from the cold room, the aqueous fraction was prepared for animal inoculation

During ether treatment, precautions were taken to reduce absorption by the extract of oxygen from the air The cysteine stool extract mixture showed reduction of thionin

fraction was

ierature. If the
nder was pre-

pared for monkey inoculation, by the cerebral route

Gard's (1943 a) method The material was suspended in a suitable volume of 0.3 per cent. saline, and shaken with glass beads mechanically for 2-4 hours Further diluent was then added, and the mass extracted under mechanical stirring for 8 hours It was then *left to settle in the cold room overnight. The supernatant was siphoned off and passed* twice through the separator The clarified extract was mixed with 2/3 by volume of

suspended to the original volume in distilled water and run up and down to 16,000 r p m. The second supernatant was further fractionated in the centrifuge, alternating at 27,000 r p m. for the 70 minutes, and up and down to 16,000 r p m The Sharples type of instrument can be used if the deposit is sealed from the atmosphere (Melnick, 1946 *a*, 1947).

Silverberg (1945) has shown that virus can be sedimented at 18,000 r p m in 4 hours from stool suspension The sediment is treated with ether.

Centrifugation. Probably the best method of concentrating virus is by differential centrifugation Briefly, the method used by Melnick (1943 *a*) and coworkers (Melnick ... Ward, 1945) is as follows

at 3000 r p m, 18,000, 39,000, and finally at
ween centrifugations 1 and 2, and 3 and 4
is left in the cold for 16 hours, and then

inoculated intracerebrally.

Animal inoculation After treatment by one of the above methods, material is inoculated in susceptible monkeys intranasally, intraperitoneally, and, when the material is sterile, intracerebrally, or into the lumbar cord If possible the animal should be inoculated repeatedly, and 2 or more animals should be used (Howe and Bodian, 1942 *a*, 1944 *a*)

Bodian, 1939 *a*), in fact, this is perhaps one of the most satisfactory methods. These authors recommend the use of nembutal anesthesia, and 5 nasal inoculations, the animal being suspended head downward, for 15 minutes, the inoculation is made with a blunt needle *over the olfactory area*

of
(e
It

Intestinal Tract

Technique.

Virus may be sought in feces, or rectal washings, or in fatal cases in suspensions of the wall of the small or large intestine; at postmortem, colonic contents can be collected.

Prior to inoculation specimens can be preserved frozen, preferably in a carbon dioxide ice chest, infectivity is maintained for several months. Specimens can be mailed to the laboratory (Trask, Paul, and Vignac, 1940). If desired, specimens can be kept under ether in the ordinary refrigerator for at least 12 days (Kling *et al*, 1939 *a, b*). Usually on receipt in the laboratory the specimen is prepared for animal inoculation by one of the following methods

Desiccation from the frozen state can be used to concentrate stools (Kramer, Gilliam, and Molner, 1939).

Freezing and thawing. Fecal suspensions are strained through cheesecloth, subjected to one cycle of freezing and thawing, and lightly centrifuged. The supernatant is used for inoculation (Howe and Bodian, 1940 *a, b*).

Precipitation and dialysis Virus in aqueous suspensions of stool can be concentrated by precipitation with 50 per cent saturation of ammonium sulfate, and subsequent dialysis (Gard, 1940 *a*) Virus has been recovered also by precipitation of proteins at the isoelectric point, ether is added and inoculation carried out with the middle layer (Herriott and Francis, 1943).

Etherization Many workers have made use of ether as a means of destroying intestinal bacteria without affecting the virus (e g., Kling *et al*, 1939 *a, b;* Lépine, 1939, McClure, 1941 *a, c;* Paul and Trask, 1941).

Trask, Paul, and Vignec (1940) recommend breaking up the stool with 5-10 times its weight of cold distilled water. After a few hours in the cold, the supernatant is pipetted into flasks with glass beads, and 10-15 per cent. of ether by volume added. The flasks are shaken and kept in the cold overnight. The contents are pipetted into 50 c.c. tubes and centrifuged at 1000 r p.m. for 20-45 minutes. The middle layer is pipetted off, and held in the cold till inoculated If desired, fluid can be concentrated by lyophilization

A simple technique was used by Paul, Havens, and van Rooyen (1944). A 10 per cent suspension of 5 gm of stool is prepared in sterile distilled water. It is allowed to settle at room temperature, and the supernatant fluid is then divided into 2 parts. One part is kept at refrigerator temperature, and instilled (3 c.c.) into the nostrils of a monkey on 3-4 successive days The other part is centrifuged for 20 minutes at 2000 r p m, and 15 per cent. ether is added to the supernatant The etherized suspension is kept in the refrigerator for 48-72 hours, and 15-20 c c inoculated intra-abdominally in a monkey.

Fisher (1943) used the following method, working in Craigie's laboratory.

(*a*) Anesthetic ethyl ether (1 volume), taken from an unopened metal container kept at 5° C in the dark, was shaken with 2 changes of neutral distilled water (2 volumes) in a 250 c c separatory funnel for 5 minutes

(*b*) Cysteine hydrochloride was freshly prepared in a primary dilution of 1 50 The crystals were first dissolved in 1 c c of neutral distilled water and then 5 c c of 0 6 M Na_2HPO_4 were added The pH of this mixture was 4 3 The cysteine solution was then diluted to requisite volume by the addition of 0 06 M. sodium potassium phosphate buffer at pH 7 0 The resulting pH was 5 7

(*c*) A weighed amount of stool material was well triturated in a mortar with 0 85 per cent aqueous solution of sodium chloride, whic
the process, until a dilution of 1 10 was obtained T
in an angle head centrifuge for 30 minutes at 3,00
2/3 of the supernatant was removed to a separato
were added 5 c c of the cysteine hydrochloride solution to give a final dilution of the latter of 1 500 The pH of the stool extracts was remarkedly uniform being from 6 8 to 7.2, when tested colorimetrically with bromthymol blue However, on the addition of the cysteine solution the pH shifted to a range of from 6 0 to 6.4, at which pH the extract was treated with ether

(*d*) One volume of washed ether was added to 2 volumes of stool extract in the separatory funnel, and shaken for 5 minutes Following a 5 minute settling period, the

periods in the stool, and Lucas and Osgood (1913) found virus in the nasal secretion some months after an attack.

Carriage by contacts. It is now quite clear that poliomyelitis virus becomes widely distributed in the environment of abortive or paralytic cases of the disease Thus virus has on occasions been recovered from the nasopharynx of intimate contacts, especially members of the same family and playmates (Flexner, Clark, and Fraser, 1913, Kling and Pettersson, 1914, Melnick, Horstmann, and Ward, 1946) In another study, however, virus was not found in the nasopharynx, even though the stools were positive (Brown, Francis, and Pearson, 1945). Howe and Bodian (1947 *a*) recovered virus from the throats of at least 2/28 healthy children in distant contact with a source of infection Virus has more frequently been recovered from the stools of intimate contacts (Kramer, Gilliam, and Molner, 1939, Kessel *et al*, 1941, McClure, 1941 *c*, Piszczek *et al*, 1941; Top and Vaughan, 1941, Howitt, Buss, and Shaffrath, 1942, McClure and Langmuir, 1942; Langmuir, 1942; Brown, Francis, and Pearson, 1945, Gear, Yeo, and Mundel, 1945, Pearson and Rendtorff, 1945 *a, b*, Gear and Mundel, 1946, Casey *et al*, 1947).

While some of these contacts develop abortive, and a few paralytic, poliomyelitis, many remain in apparent health. It can be said, therefore, that "healthy" carriers of poliomyelitis definitely exist These persons probably remain carriers for only a short while, yet may disseminate the infection in the meantime, they probably carry the virus for the same length of time as do cases. For example, Piszczek *et al.* (1941) found virus in the stool 2 months after contact

The majority of positive isolations of virus in contacts has been from children, who seem to be more liable to "pick up" the virus than adults. Even infants may be "healthy" carriers (Kramer, Gilliam, and Molner, 1939, Pearson and Rendtorff, 1945 *b*) Nevertheless, various workers have detected virus in the stools of adults in contact with cases Thus virus has been isolated from nurses (Kramer, Gilliam, and Molner, 1939, Landsberg, 1945). Langmuir (1942) recovered virus from the stools of 4/8 adults who were intimate contacts of the cases Pearson *et al.* (1945) found virus to be harbored by adults in 5/6 households where a case occurred

Carriage by noncontacts The available evidence shows that the virus enjoys a limited distribution in close relation to cases of the disease. It is found only rarely in the secretions of persons with no known contact with poliomyelitis Thus Pearson and Rendtorff (1945 *a*) examined the pooled feces of over 100 persons in a village The only positive was the 6-year-old son of a patient. In another outbreak, a larger number of stools was examined, and again the positives were found to have some personal association with cases, with one exception (1945 *b*) Similar negative results with the stools of noncontacts have been recorded by others (Trask, Paul, and Vignec, 1940, Piszczek *et al*, 1941, McClure and Langmuir, 1942). The stools of persons suffering from other diseases have also been examined as controls, and found negative (*Paul, Havens, and van Rooyen, 1944*).

However, certain observations show that on occasions the virus may be recovered from persons with no known contact with cases of poliomyelitis Thus virus [illegible]

[illegible] posure

[illegible] known

[illegible] groups

[illegible] 5/136

persons harbored virus either in the tonsils or stool. These latter findings suggest that perhaps the virus enjoys a wider distribution than has been believed hitherto

"Incubating" or "precocious" carriers Persons harboring virus in the nasopharynx may later develop symptoms of poliomyelitis (Taylor and Amoss, 1917). Virus was detected in the stool of a boy who 12 days later developed clinical poliomyelitis (Gear and Mundel, 1946), and of another person who became ill 19 days later (Brown, Francis, and Pearson, 1945) Obviously these persons may infect other persons during their incubation period (see Gear and Mundel, 1946).

paralytic, excretes virus in the feces for at least a brief period, and numbers of workers have isolated virus from such persons (e g, Kling, Wernstedt, and Pettersson, 1911–12; Harmon and Levine, 1936–7; Kling, 1938 *b*, Trask, Vignec, and Paul, 1938 *a*, *b*; Kling *et al.*, 1939 *a*, *b*, *Kramer, Hoskwith, and Grossman, 1939*, Lépine and Sédallian, 1939, Toomey, 1939 *c*, Howe and Bodian, 1940 *a*, 1942 *a*, Trask, Paul, and Vignec, 1940; Kempf and Soule, 1941; Kessel *et al*, 1941; McClure, 1941 *a*, *c*, Paul and Trask, 1941; Sabin, 1941 *b*, Sabin and Ward, 1941 *d*, *e*; Howitt, Buss, and Shaffrath, 1942, McClure and Langmuir, 1942; Paul, Havens, and van Rooyen, 1944; Silverberg, 1945; Gear and Mundel, 1946; Horstmann, Melnick and Wenner, 1946, Melnick, Horstmann and Ward, 1946, Ward, Horstmann and Melnick, 1946). Melnick (1947) has calculated that a 100 gm. stool may contain 1000–*10,000 monkey infectious doses*.

Virus has been found in the wall of the ileum, and less commonly of the descending colon (Sabin and Ward, 1941 *d*). Wenner and Paul (1947) isolated virus from the duodenal wall in 2 cases.

Effect of age. Virus has been found by some workers more readily in the stools of patients under 8–16, than in those of older persons (Trask, Paul, and Vignec, 1940, Kessel *et al.*, 1941, Sabin, 1941 *b*, Sabin and Ward, 1941 *e*). Horstmann, Ward, and Melnick (1944, 1946) found, however, that age played no part. Even infants (under 2) may excrete virus (McClure, 1941 *c*).

Duration of infectivity.

Virus has been found in the stools of an abortive case 2 days after onset (Ward, Horstmann, and Melnick, 1946), and on the day of onset of a paralytic case (Zintek, 1947). During the first week it is probable that all cases of abortive and paralytic poliomyelitis excrete virus, thereafter the number excreting steadily falls For example, *Horstmann, Ward, and Melnick (1944, 1946) studied the duration of* excretion of virus in 46 paralytic and 15 abortive cases, and found the following percentages of excretors in the various weeks first 2 weeks, 60–70 per cent, 3rd and 4th weeks, 50 per cent, 5th and 6th weeks, 27 per cent.; 7th and 8th weeks, 13 per cent, between the 9th and 24th weeks, virus was detected in only 1 specimen, at the 12th week

Other records of prolonged excretion are as follows. 50 days (Howitt, Buss, and Shaffrath, 1942), 2 months (Kessel *et al*, 1941), 123 days (Lépine, Sédallian, *and Sautter, 1939*)

We may conclude that virus can be found in the stools of abortive and paralytic cases equally, from shortly after onset until up to 3 months later, the majority ceasing to excrete in 1–2 months There is no evidence that virus is excreted for periods as long as a year or more (see, e g, Howitt, Buss, and Shaffrath, 1942)

Source of virus It has been suggested that virus in the stool is only derived from the nasopharynx, where it is present for a few days at the onset of the disease As virus has been isolated from the wall of the gut, and as it persists in the stool *long after it has disappeared from nasopharyngeal washings*, this does not appear very likely (Sabin, 1941 *b*, Sabin and Ward, 1941 *e*) Howe and Bodian (1942 *a*) suggest that virus is derived either from nerve cells of the intramural plexuses, from lymphocytes passing through the wall of the gut, or from epithelial cells of the mucosa It appears possible that virus may actually proliferate in epithelial cells of the intestine (see Evans and Green, 1947)

CARRIERS OF POLIOMYELITIS VIRUS

Convalescent carriers It is not thought that true convalescent carriers exist at all commonly, as all the evidence suggests that virus is present in the nasopharynx for only a few days, and in the stools for some weeks It is possible, however, that a very small percentage of persons may excrete virus intermittently over long

afferent systems of the 5th, 7th, 9th, and 10th cranial nerves, the first neuron is in the peripheral ganglia, while the first synapse is in the pons or medulla. With the sympathetic system the first neuron and synapse occur in the ganglion, while in the vagal efferent (parasympathetic) system the first neuron and synapse are in the intramural microganglia, very close to the mucous membrane. The best method of detecting the portal of entry, therefore, is to examine the site of the first neuron, in olfactory bulb, brain, or ganglion It must, however, be realized that changes in

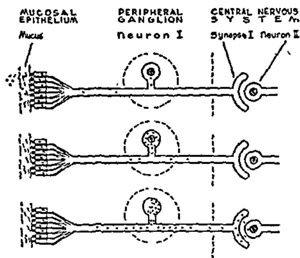

Fig 41 Route of invasion of poliomyelitis virus Schematic representation of invasion of a unipolar neuron with branched axon (e g, a trigeminal afferent unit of the gasserian ganglion) by virus particles (solid dots) through the epithelial surface, with subsequent central spread of infection Virus particles are caught in the mucus covering the epithelium, enter the superficial arborizations of the axon, course through the axon into the nerve cell (Neuron I) where they multiply, set up the primary lesion, then spread centrally, break through the synaptic membrane, and infect Neuron II Logically they may be expected also to course outward again to the surface, as in the lower figure, thus possibly accounting for the appearance of virus on the surface during the early clinical manifestations of the disease

(Reproduced from *J. exp. Med*, 1946, 83, 329)

ganglia may be produced not only by centripetal spread, when they are found early, but also by centrifugal spread at a later stage of infection (see also Bodian and Howe, below).

Faber and Silverberg visualized the invasive process as proceeding in steps (1) invasion of peripheral fibers into regional
tioned), (2) invasion of connecting center in
via short connecting neurons, (4) invasion of
and central sites of infection, presumably by
a detailed histological study of 8 fatal cases
their results as follows (*a*) the trigeminal (5th cranial) nerve afferent system (nose, mouth, pharynx) was very frequently involved (*b*) The visceral afferent

PATHOGENESIS OF HUMAN POLIOMYELITIS

Experimental

Theories of the pathogenesis of human poliomyelitis have resulted very largely from experimental work carried out on monkeys, rather than on observations in the patient. It is probable that in certain respects, work on monkeys has proved definitely misleading, particularly as suggesting that the olfactory route is commonly followed in the human subject. The main points that have been shown experimentally will be summed up here, but a fuller discussion will be found in the section on the pathogenesis of experimental poliomyelitis (see p. 988), and elsewhere in the sections devoted to the virus and its properties.

(*a*) The monkey can be readily infected by nasal instillation, and the virus spreads along the olfactory nerve fibers After a few days, both virus and histological changes can be demonstrated in the olfactory bulbs. Thereafter, the virus spreads to other parts of the central nervous system, and can be demonstrated successively in the thalamus, hypothalamus, medulla, cervical and lumbar cords (see p. 976).

(*b*) Although animals can be infected intrathecally, the cerebrospinal fluid is not held to play any part in the primary dissemination of the pathogenic agent.

(*c*) The monkey can be infected only with difficulty by the blood stream, and the blood is not usually responsible for the spread of the virus when it is injected by other routes

(*d*) Although earlier workers failed to infect by the gastro-intestinal tract, Toomey and others have recently succeeded in infecting by ingestion, pharyngeal swabbing, or direct injection.

In brief, the position on the experimental side is that virus spreads by axonal routes from the site of inoculation to the central nervous system. Arrived at the central nervous system, the primary attack of the virus is on the nerve cell, and there is no evidence that the degeneration which these cells undergo is in any way secondary to meningitis, or to interstitial lesions. The virus is present in the central nervous system from the beginning, and there is no stage of general infection with the presence of virus in the blood.

Portals of Entry and Spread of the Virus in Man

It is uncertain as to how poliomyelitis virus enters the human body. This question is intimately linked with epidemiology, and it is of considerable importance to discuss in some detail the various possible portals. This question has been studied for many years by Faber, whose opinions must be regarded as authoritative According to his latest views, the following possible portals of entry must be considered (Faber and Silverberg, 1946) the olfactory area, the nose, mouth, and pharynx, the tracheobronchial tree, the esophagus, the stomach and intestine proximal to descending colon, the distal colon, sigmoid, and rectum. (See Figs 41 and 42, from his paper) Faber and Silverberg presume that virus entering at any one of these sites invades the superficially situated axons of a nerve cell, and passes along the fibers to the first neuron (nerve cell), where it multiplies It is not thought likely that nerves without a superficial connection are likely to transmit the virus, with the exception of motor nerves in the pharynx after tonsillectomy The first neuron may have other axons passing directly to the brain where the first synapse occurs In other cases the first synapse occurs at the site of the first neuron. It is probable that the synapse represents a definite barrier to the progress of the virus, so that the synapse may show early lesions associated with invasion

In the case of the olfactory system, the first neuron is in the nasal mucous membrane, and the first synapse in the olfactory bulb In the mesencephalic trigeminal system the first neuron and synapse are in the midbrain In the case of the

in the mucous surfaces can, if exposed, convey virus centrally. There was evidence of entry through the nose, mouth, or pharynx in nearly all cases, and through the upper tracheobronchial tree or esophagus in several

CNS They suggested that ganglionic lesions could be caused by centrifugal, rather than centripetal, spread Another complication arises from the probability that virus can spread along nerves without producing changes in ganglia Faber and Silverberg found lesions in a number of ganglia and therefore postulated several portals of entry in a single patient Bodian and Howe mention that the 5th, 7th, and 9th cranial nerves serving the oropharynx, and the 10th nerve supplying the lower alimentary tract are the most likely routes of passage of virus to the CNS They conclude that the specificity of lesions in the sympathetic ganglia has not been established, and that the presence of lesions in the sensory ganglia does not reveal whether the virus reached the ganglia from the periphery or center, except in very early cases

It now falls to record a number of other observations regarding the rôle of the various possible portals of entry.

1. *The nose.* Virus has quite frequently been recovered from throat washings in abortive and paralytic poliomyelitis, and has been recovered from the tonsil, the nasal secretion seems to be less regularly infected (see p 928). Virus can usually be found in the nasopharynx in the first few days of the illness, and has been found in close contacts and "incubating carriers" Such persons must, therefore, exhale droplets of secretion infected with virus The symptoms of the illness of infection suggest upper respiratory involvement. Further, poliomyelitis seems sometimes definitely to be precipitated by respiratory infection. In some cases, the first symptoms of the declared disease are respiratory.

There is, therefore, evidence suggesting that the olfactory nerves must be seriously considered as a portal of entry The olfactory nerve endings lie exposed in the upper part of the nasal cavity, and virus present in the nose might readily come in contact with these structures The further spread of the virus would presumably be by the olfactory bulbs, olfactory bundle, fibers passing to the thalamus and tegmentum, and from the midbrain, by the spinothalamic tract to the posterior horn, from the posterior horn, fibers connect with the anterior horn (Harbitz and Scheel, 1907 *a*, *b*, Flexner, 1915, Faber, 1933) It has been mentioned that the clinical features of Phase 1 and 2 may be explicable by successive involvement of the *thalamus and hypothalamus and the sensory column* (Faber, see p 923).

Against the olfactory route as a common portal of entry, however, are certain important observations Thus, histological changes occur only rarely in the olfactory bulbs (see 942), and virus does not appear to be regularly present in these structures (see p 928). Further, trials of chemical substances intended to "block" the spread of infection by the exposed olfactory nerves have been a failure (see p 966)

A few years ago the balance of opinion was in favor of accepting the olfactory route as the common portal of entry (see, e g, Flexner, 1931 *b*), but few now hold this view. Faber and Silverberg (see above) in histological studies found no support for the concept of entry by olfactory nerves, but concluded that virus commonly entered through the nose and nasopharynx, involving the trigeminal afferent system, and the visceral afferent system of the 9th and 10th cranial nerves

system of the 9th and 10th cranial nerves (nose, mouth, pharynx, esophagus and bronchi, stomach and intestines) was fairly commonly involved. (*c*) The gustatory system (7th, 9th, and 10th cranial nerves) was occasionally involved. (*d*) The sympathetic system was occasionally involved (i e, pharynx, bronchi, esophagus, intestines). (*e*) The vagal efferent or parasympathetic system and the olfactory system were not involved.

In general, the evidence of penetration through the upper alimentary and

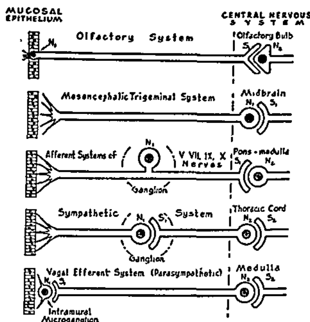

FIG 42 Route of invasion of poliomyelitis virus Schematic representation of the various potential nerve pathways of infection, showing the different arrangements of neurons (N_1, N_2) and synapses (S_1, S_2) in relation to the mucous surfaces, peripheral ganglia, and central nervous system Note unique position *inside the central nervous system* of the primary neuron of the mesencephalic trigeminal system Its peripheral endings are, however, deep from the surface, making them relatively inaccessible to surface virus except under special circumstances, such as are discussed in the text

(Reproduced from *J exp Med*, 1946, *83*, 329)

respiratory tracts was more obvious than through the lower alimentary tract Evidence for intestinal entry through the sympathetic was ambiguous, but there was little evidence of infection ascending to the CNS by this route The pharynx appeared to be a specially favorable site for the primary penetration of the virus Primary invasion through the sympathetic system results in initial involvement of the CNS at the spinal level, invasion through the other channels results in initial involvement of the CNS at the brain stem level In neither instance does the level of this initial involvement necessarily determine the site of initial paralysis

They concluded that there appears to be no single portal of entry in human poliomyelitis, on the contrary, their evidence suggested a variety. The earlier concept of an exclusive channel for all cases, either olfactory or intestinal, is, therefore, contradicted. Apparently almost any nerve system with peripheral endings

in the mucous surfaces can, if exposed, convey virus centrally. There was evidence of entry through the nose, mouth, or pharynx in nearly all cases, and through the upper tracheobronchial tree or esophagus in several

It is uncertain how much value can be attached to deductions based on changes in ganglia, and Bodian and Howe (1947) have come to somewhat different conclusions from those of Faber and Silverberg. They found no lesions that could be considered specific in complete serial sections of 16 pairs of celiac ganglia, and 11 pairs of stellate ganglia from fatal human cases. There were abundant lesions, however, in some of the trigeminal and spinal sensory ganglia. The intensity of the lesions coincided relatively well with the intensity of the lesions in the adjacent CNS. They suggested that ganglionic lesions could be caused by centrifugal, rather than centripetal, spread Another complication arises from the probability that virus can spread along nerves without producing changes in ganglia. Faber and Silverberg found lesions in a number of ganglia and therefore postulated several portals of entry in a single patient Bodian and Howe mention that the 5th, 7th, and 9th cranial nerves serving the oropharynx, and the 10th nerve supplying the lower alimentary tract are the most likely routes of passage of virus to the CNS They conclude that the specificity of lesions in the sympathetic ganglia has not been established, and that the presence of lesions in the sensory ganglia does not reveal whether the virus reached the ganglia from the periphery or center, except in very early cases

It now falls to record a number of other observations regarding the rôle of the various possible portals of entry.

1. *The nose* Virus has quite frequently been recovered from throat washings in abortive and paralytic poliomyelitis, and has been recovered from the tonsil, the nasal secretion seems to be less regularly infected (see p 928). Virus can usually be found in the nasopharynx in the first few days of the illness, and has been found in close contacts and "incubating carriers" Such persons must, therefore, exhale droplets of secretion infected with virus The symptoms of the illness of infection suggest upper respiratory involvement Further, poliomyelitis seems sometimes definitely to be precipitated by respiratory infection. In some cases, the first symptoms of the declared disease are respiratory

There is, therefore, evidence suggesting that the olfactory nerves must be seriously considered as a portal of entry. The olfactory nerve endings lie exposed in the upper part of the nasal cavity, and virus present in the nose might readily come in contact with these structures. The further spread of the virus would presumably be by the olfactory bulbs, olfactory bundle, fibers passing to the thalamus and tegmentum, and from the midbrain, by the spinothalamic tract to the posterior horn, from the posterior horn, fibers connect with the anterior horn (Harbitz and Scheel, 1907 *a*, *b*, Flexner, 1915, Faber, 1933) It has been mentioned that the clinical features of Phase 1 and 2 may be explicable by successive involvement of the thalamus and hypothalamus and the sensory column (Faber, see p 923)

Against the olfactory route as a common portal of entry, however, are certain important observations Thus, histological changes occur only rarely in the olfactory bulbs (see 942), and virus does not appear to be regularly present in these structures (see p 928) Further, trials of chemical substances intended to "block" the spread of infection by the exposed olfactory nerves have been a failure (see p 966)

A few years ago the balance of opinion was in favor of accepting the olfactory route as the common portal of entry (see, e.g, Flexner, 1931 *b*), but few now hold this view Faber and Silverberg (see above) in histological studies found no support for the concept of entry by olfactory nerves, but concluded that virus commonly entered through the nose and nasopharynx, involving the trigeminal afferent system, and the visceral afferent system of the 9th and 10th cranial nerves.

Other histological studies have failed to incriminate the olfactory portal (Swan, 1939, Robertson, 1940, Howe and Bodian, 1941 *d*, 1942 *a*).

2. *Mouth and pharynx.* Numerous cases of bulbar poliomyelitis have followed tonsillectomy (see p. 920). It is probable also that trauma associated with the cutting of teeth may allow the entrance of virus into nerve fibers It has been suggested also from clinical observation and experiments in monkeys that pulpal exposure may act as a predisposing factor (Aisenberg, 1946; Aisenberg and Grubb, 1943, 1945) Virus has been isolated from the tonsil and nasopharyngeal secretions in healthy contacts, incubating carriers, and cases of paralytic or abortive infection There is every reason to postulate, therefore, that the mouth and pharynx may be a common portal of entry in ordinary cases of poliomyelitis, and Faber and Silverberg found evidence of entry through the nose, mouth, or pharynx in nearly all cases. These workers suggested that the nasopharynx and oropharynx are probably *the most important portals of entry, and are infected either by mucous* drainage from the nose or by material entering the mouth. Virus spreads back to the CNS via the trigeminal afferent, 9th and 10th afferent, or less commonly the gustatory system Other workers have also obtained evidence by histological examination that cranial nerves connected with the pharynx may act as portals of entry in ordinary cases (Robertson, 1940; Howe and Bodian, 1941 *d*, 1942 *a*, Sabin, 1941 *a*, 1942).

In cases of primary bulbar poliomyelitis, not connected with tonsillectomy, it is probable that the virus spreads to the medulla by invasion along the 5th, 7th, 9th, and 10th cranial nerves (Sabin, 1942) and not by the sympathetic pathway.

3. *Tracheobronchial tree* Virus has been recovered from tracheal exudate, and apart from this the common presence of virus in the upper respiratory passages suggests the possibility of invasion through the mucosa of the trachea and bronchi The only observations are those of Faber and Silverberg who concluded that several cases showed evidence of entry through the upper tracheobronchial tree (as well as by the nose, mouth, and pharynx). The paths involved are the visceral afferent system of the 9th and 10th nerves, or the sympathetic system

4 *The gastro-intestinal tract* The gastro-intestinal symptoms of the preparalytic stage, and the presence of lesions of the follicles and Peyer's patches, led many authors to suggest that the virus enters the body by the gastro-intestinal tract (e g, Harbitz and Scheel, 1907 *a*, *b*, Wickman, 1907, Krause, 1909, Dahm, 1909, Burrows, 1920, 1931, Kling, Levaditi, and Lépine, 1929, Toomey, 1931–2 *c*, 1933, 1934 *a*, Kling, 1937, Gard, 1937, 1938).

With the knowledge of the relative ease with which virus can be isolated from the feces of cases and contacts, there is every justification for this suggestion Experiments conducted *in vitro* indicated that at high levels of acidity, e g, *pH 1 0*, virus is completely inactivated in 5 minutes, at pH 2 0 inactivation is not complete for 4 hours Conditions of high acidity as occur after ingestion of carbohydrate or meat, therefore, favor inactivation Milk would tend to prevent inactivation. It appears, therefore, that ingested virus may not uncommonly reach the intestine (Faber and Dong, 1946). It has been held that virus travels to the cord by the sympathetic system, and Toomey has followed up this suggestion of older workers (1936 *f*)

One of Toomey's main points is that the virus has a special affinity for gray fibers Medullated fibers contain very much more cholesterol than gray fibers Accordingly, as it has been found that cholesterol inactivates the virus *in vitro*, he has postulated that medullated fibers offer a certain resistance to the spread of the virus, but on occasions this may be overcome Toomey suggests that the virus of poliomyelitis enters the body through naked nerve endings Such a distribution of fibers exists in the nose, the gut, and in the terminal ramifications of the chorda tympani Toomey believes that the observed facts of poliomyelitis are best explained

by postulating entry through the gut In certain cases, however, virus may enter the body through nerve endings in the mouth, and give bulbar symptoms.

The virus is said to spread from the gastro-intestinal tract by the sympathetic gray fibers and somatic nerves and, as the virus has an affinity for gray fibers one would expect that the parts of the body to be most commonly involved would be the legs, because between the 3rd lumbar and 2nd sacral segments only gray fiber connections appear Elsewhere, the white rami communicantes are thought to hinder the spread of virus The virus may spread up the sympathetic chain to the cervical area, where there is a similar absence of white rami communicantes, and cause paralysis of the upper extremities

As evidence of this affection of the sympathetic fibers, Toomey mentions that the bladder is often paralyzed before somatic paralyses appear Further, he relates the various reflex changes, and the results of pilocarpine injection (see above), to involvement of the sympathetic fibers.

Of recent years histological examination of the nervous system has been carried out by various workers, and has suggested to them that in many cases the virus appears to reach the cord from the bowel by nerve paths (Howe and Bodian, 1941 *d*, 1942 *a*, Sabin, 1941 *a*, 1942; Faber and Silverberg, 1946).

Sabin suggests that virus enters the body by the mouth and establishes itself in the alimentary tract, where it multiplies Invasion of the CNS occurs along 2 paths One path passes to the medulla by way of the cranial nerves or by way of the parasympathetic system of the vagus The other path leads to the spinal cord along visceral afferent fibers through spinal ganglia, an alternative route is by visceral efferent fibers and the sympathetic chain.

Faber and Silverberg concluded that the evidence of penetration through the upper alimentary tract (pharynx and esophagus) was more obvious than through the lower tract There was little evidence of infection ascending to the CNS by the sympathetic system.

Although virus would appear to proliferate in the wall of the small intestine, the evidence suggests that invasion of the CNS more usually occurs from the upper alimentary tract, especially the pharynx It is possible, however, that a secondary invasion of virus may occur from the intestines, explaining the relative frequency with which lesions are found in the celiac ganglia (Faber and Dong, 1946)

There is no evidence to suggest that virus may invade through the colon and rectum.

5 *The skin* The rôle of the skin has received relatively little attention It is known that poliomyelitis has followed the subcutaneous inoculation of vaccines If mosquitoes or biting flies play any part in transmitting the disease, virus would require to be introduced into or under the skin

Wenner and Paul (1947) studied a fatal case in a technician, where the portal of entry may possibly have been a scratch on the wrist which was later soiled with virus

Possible Alternative Means of Dissemination of Virus

There is no doubt that poliomyelitis virus in man and monkey is essentially neurotropic, and invades the CNS from the portal of entry by nerve paths This method of spread has been suggested in man by histological observations, and in monkeys by various experiments. One must, however, consider certain alternative methods of invasion

1 *Cerebrospinal fluid.* It has been suggested that virus enters the cerebrospinal fluid, probably from the olfactory perineural spaces, and is disseminated thereby to the cord and other parts of the central nervous system (see Amoss, 1928) However, as the virus has not been commonly isolated from the cerebrospinal fluid, it is not easy to justify this theory.

2. *The blood* Although widely held at the beginning of the century (e g., by Lovett and Lucas, 1908, also see Wayson, 1918 *a*), this theory was mainly formulated by Draper (1917), who postulated a stage of generalized infection, with virus in the blood. It was thought that the virus caused injury to the meningeal vessels and plexuses, finally producing a generalized infection of the central nervous system. Virus has, however, only very rarely been demonstrated in the blood of human cases. The pathological lesions, moreover, do not suggest any such method of spread.

3. *The lymphatic system.* It has been known for some time that the lymphoid structures are involved in poliomyelitis (e.g , Müller, 1910, Peabody, Draper, and Dochez, 1912; Abrahamson, 1916–19 *a*, *b*). For example, the intestinal follicles are enlarged, the Peyer's patches prominent, and there is enlargement of the spleen and mesenteric lymph nodes In one case, Flexner and Lewis (1910 *d*) isolated the virus from a mesenteric lymph node (as did Kling, 1937). There is also enlargement of many other groups of lymph glands, such as the substernal and bronchial, cervical, axillary, and inguinal The tonsils are enlarged, and may contain the virus (see p. 929)

Burrows (1920, 1931), in particular, has stressed the importance of the lymphatic system and has even gone so far as to call poliomyelitis a lymphatic disease He suggests that the virus enters the body by the lymphatics of the gastro-intestinal tract, and then generalizes. He believes that perivascular lesions are primary and nerve cell lesions follow Faber (1933) suggests that the lymphatic hyperplasia is merely compensatory, to supply the lymphocytes needed both in the cord and the cerebrospinal fluid.

The Primary Tissue Reaction in Human Poliomyelitis

For many years controversy turned on what constitutes the primary reaction to the virus of poliomyelitis That nerve cell destruction is one of the most characteristic histological features of the disease was admitted by all, but the etiology of this lesion caused disagreement. One school, following the original lead of Charcot and Joffroy (1870), suggested the nerve cell lesion to be primary and independent of meningeal or interstitial inflammation (e g., Rissler, 1888, Abrahamson, 1916–19 *b*, Faber, 1933, Korn [illegible]). The other school held the nerve cell lesion to b[illegible] or perivascular cellular infiltration (e g., Roger [illegible] 1907, 1913, Harbitz and Scheel, 1907 *a*, *b*, Peabody, Draper, and Dochez, 1912) The question is difficult to solve from examinations of human autopsy material only, for at the time of death, lesions are so far advanced that it is not possible to state whether neuronal or interstitial change is the primary. But the work of Hurst and of Fairbrother (*vide infra*) on the pathogenesis and histology of experimental poliomyelitis, has shown conclusively that the nerve cell lesion is primary and quite independent of interstitial changes In our opinion, this is the only view that can be taken of the primary tissue reaction in human poliomyelitis, and is supported by later observations (Sabin, 1942, Elliott, 1945, Bodian, 1947)

PATHOLOGY

Numerous workers in many parts of the globe have reported the results of their pathological examinations, and the resulting picture is extremely uniform (e g, Forssner and Sjovall, 1907, Harbitz and Scheel, 1907 *a*, *b*, Wickman, 1907, Cadwalader, 1908, Peabody, Draper, and Dochez, 1912, Muller, 1910, Abrahamson, 1916–19 *b*, Burrows, 1920, 1931, McIntosh and Scarff, 1928, Marinesco, Manicatide, and Draganesco, 1929, Cappell, 1930–1, Wolf and Orton, 1932, Spielmeyer, 1932, Horányi-Hechst, 1935, Harmon and Levine, 1936–7, Peters, 1938, Swan, 1939, Sabin, 1942, Peers, 1943, van Rooyen and Morgan, 1943, Elliott, 1945, 1947, Faber and Silverberg, 1946, Luhan, 1946, Bodian, 1947, Scheinker, 1947).

Central Nervous System

To the naked eye, the brain and cord appear superficially congested. On section the cord is edematous, and the gray matter congested and sharply demarcated from the white

Types of lesion.

1. *Changes in the nerve cells.* It has been mentioned that nerve cell lesions are now regarded as primary, not secondary They are present even in the pre-paralytic stage, but do not attain any great intensity until the paralytic stage.

In the cord, the cells mainly affected are those of the anterior horn, although numerous cells in the posterior horn and ganglia are involved as well The changes vary from simple chromatolysis to complete destruction, cells which are no longer viable undergo neuronophagia, microglia and polymorphs removing all traces Cells which are not severely damaged, perhaps by edema only, presumably recover their function, thus accounting for the return of power to originally paralyzed limbs Sabin (1942) points out that the segmental distribution of the lesions may be so irregular as not to affect the major innervation of a given muscle After the lapse of time, if there has been much destruction of nerve cells, the horn becomes shrunken and atrophied The former site of the cells is occupied by glial tissue Necrosis of nerve cells occurs in the cerebral cortex, but is said to be confined to the Betz cells of the area giganto-pyramidalis (Swan, 1939).

Elliott (1945, 1947) has examined the nerve cells in the spinal cord in chronic and acute cases Lesions appeared to begin in the dorsal and medial nuclei and spread ventrolaterally. The degree of involvement varied from small localized foci to almost complete loss He suggested that the differential infection of nuclei was due not to their proximity to a source of infection, nor to their intrinsic suscep [illegible]

2 [illegible]

lesions [illegible]

(Bonh [illegible]

bodies do not show advanced degenerative change. The bodies are small eosinophilic granules measuring up to 3 to 5 μ in diameter The affected nucleus usually shows margination of the basichromatin Wolf and Orton have found similar bodies in a number of other diseases, and they would appear to resemble other well-known intranuclear inclusions, especially those of yellow and Rift Valley fevers.

3 *Perivascular infiltration* The vessels in the parenchyma of the cord, and to a lesser extent elsewhere, show "cuffing" The vessels mainly affected are those near the anterior and posterior median fissures and at the tips of the horns The predominant infiltrating cell is the lymphocyte, but some polymorphs and plasma cells are often seen.

4 *Focal and diffuse infiltrations.* The substance of the cord and certain other parts of the central nervous system show focal and more diffuse infiltration with lymphocytes, polymorphs, and particularly with microglia This microglial proliferation is a marked feature, and it is only comparatively recently that the true nature of these cells has been realized Older authors alluded to them as "polyblasts," "elongated glial cells," and by other names, and suggested their derivation from the lymphatic system.

[illegible]

mar [illegible]

eve [illegible]

been previously injected intrathecally (Burrows, 1920).

Distribution of the lesions.

The regions most frequently involved are as follows, according to Sabin (1942), Bodian (1947), and others.

1. *The cord.* The lesions are most marked in the cervical and lumbar enlargements, and occur mainly in the anterior horn, although the posterior and intermediate horns are also involved. In acute bulbar cases, there may be no changes in the anterior horns, with some neuronophagia in less acute cases.

2. *The ganglia and nerves.* Cellular infiltrations occur in the gasserian and posterior root ganglia, and in the posterior and anterior nerve roots There is usually some loss of sensory neurons in the posterior root ganglia Marinesco and Draganesco (1932) found the ganglionic lesions to be as prominent as those of rabies.

3. *The medulla* In spinal cases changes occur in the vestibular nuclei, reticular formation, and the nuclei of various cranial nerves. In acute bulbar cases there is a marked incidence of neuronal lesions in the region of the nucleus ambiguus, dorsal motor nuclei of the vagus and nucleus solitarius, lesions become fewer as the cord is traced down (see also Goodpasture, 1925).

4. *The cerebellum* shows lesions in the roof nuclei and vermis (see also Burrows, 1920).

5. *The midbrain* shows changes in the periaqueductal gray matter, the tectum and tegmentum (see also Harbitz and Scheel, 1907 *a*, *b*; Burrows, 1920).

6. *The basal ganglia.* The hypothalamus and thalamus show cellular infiltrations

7. *The globus pallidus* shows lesions.

8 *The cortex* does not usually show much change, but lesions are concentrated in Brodmann's area No 4. Luhan (1946) has drawn attention to the frequency of changes in the motor area

9. *The olfactory bulbs.* [illegible]
tions been demonstrated,
and Smith, 1934, Harmon
De Groat, 1938, Swan, 1939, Robertson, 1940, Sabin, 1940, Luhan, 1946)

10. *Distribution of brain lesions.* Bodian (1947) found in a series of 24 cases that the centers most frequently severely damaged were the cerebellar roof nuclei, vestibular nuclei, and the reticular formation. Severe lesions in this group may superimpose on muscles weakened by imperfect spinal innervation, varying degrees of altered suprasegmental control, clinically appearing as varying degrees of hyper- or hypo-tonia, ataxia, tremor, and weakness

He found brain lesions in all 24 cases, most severe in the brain stem and not the cortex. Great variations occurred in the severity of the lesions in the brain, but the same centers were generally involved in all cases

Residual lesions.

Full descriptions of the residual lesions have seldom been published, although a few observations have been made (see International Committee, 1932) Peers (1943) has given the following account of 3 cases surviving for 7, 15, and 18½ weeks from the time of onset In the cerebral cortex there were perivascular collars of lymphoid cells and interstitial foci of microglia and astrocytes *confined to the paracentral lobules.* There was probably some diminution in the Betz cells One case showed thromboses in small vessels, with patches of recent infarction at the vertex The basal ganglia and thalami showed only minimal lesions. In the midbrain the substantia nigra was severely affected Perivascular infiltration and collections of astrocytes and microglia were found in the lateral tegmental and red nuclei There was a loss of nerve cells in Deiter's nuclei and the motor nuclei of the 5th and 7th nerves.

The longer the convalescence, the less was the perivascular infiltration, and the greater the gliosis

In the cerebellum there were some cell loss and astrocytic hyperplasia in the tectal nuclei and cortex of the vermis

In the medulla there were cell loss and scarring in the reticular substance, and a few dead nerve cells could be seen

The cord showed an almost complete loss of nerve cells through the whole length of the anterior gray substance. The lateral horns were comparatively spared. The anterior horns showed a replacement gliosis. A few necrotic nerve cells were still seen at 7 weeks. The white matter showed a mild diffuse demyelination of most of the ventral and lateral columns, excepting the pyramidal tracts. In the posterior columns, the partial demyelination was confined to the region of Schultze's tracts. Much of this degeneration was due to factors other than loss of the known cells of origin.

The anterior nerve roots showed severe degeneration consequent upon loss of the anterior horn cells Almost all the motor fibers had disappeared In contrast, the fine myelinated efferent sympathetic fibers were chiefly spared. At 7 weeks the nerve tubes contained many fat-laden phagocytes, which had disappeared by [illegible] ganglia there were a very [illegible] only a few cells had disap- [illegible] rs. Flynn (1946) examined [illegible] of the anterior and lateral horns were replaced by granulation tissue The muscles showed an extreme degree of atrophy of degeneration.

Other Organs

The muscles. The pathological changes in muscle are brought about in 2 ways (Hipps, 1942) Denervation gives rise to atrophy, degeneration, and replacement. Lesions can also occur secondarily from changing tension. Too much tension gives tears and resultant fibrosis, while too little gives changes identical with denervation These secondary lesions may produce just as much weakness in a muscle as the primary changes due to denervation. Secondary changes following immobility and disuse are more severe than those after overactivity. That primary changes may occur in the muscles, as believed by Kenny (see above) is partly suggested by the observations of Carey *et al.* (1944) on 3 cases dying of bulbar poliomyelitis They found practically complete denervation of the extrafusal muscle fibers at the myoneural junction in respiratory muscles, within 36 hours of the onset of symptoms This myoneural change was undoubtedly the terminal result of a pathological process occurring in the incubation period During the first week of illness, there was a striking passive hyperemia of the capillaries in some muscles Many fibers showed a granular and hyaline degeneration. There was a proliferation of the perivascular reticulo-endothelial mesenchyme leading to the differentiation of epithelial-like lipoblasts. The subcutaneous fat of the neck was undergoing regressive defatting changes and proliferation

The lymphatic system It has already been mentioned that there is considerable lymphatic hyperplasia in poliomyelitis Thus the Peyer's patches are ulcerated, the follicles prominent, and the spleen enlarged. Histologically, these structures are congested and the follicles are filled with granular necrotic material (see Burrows, 1920, 1931, International Committee, 1932).

The lungs The commonest cause of death is respiratory paralysis, and consequently there are found very frequently congestion and edema, or definite pneumonia (see International Committee, 1932, Saphir, 1945).

The remainder of the body. Some congestion and occasional cellular infiltrations are found in the heart, liver, and kidneys Saphir (1945) records the presence of myocarditis (see also Wenner and Paul, 1947)

Laboratory Diagnosis

The cerebrospinal fluid should be examined from the earliest stages of the infection, with particular reference to the cell count and estimation of protein

There is no object in endeavoring to isolate the virus from the cerebrospinal fluid If the case proves fatal, part of the cord should be retained for histological examination, and the remainder sent, in glycerol, to a laboratory where monkey inoculation can be performed Attempts may be made to isolate virus from the nasopharynx and stools, using the methods of concentration already described

In convalescence, the serum may be sent to a research laboratory for the virus neutralization test, and it may be possible to carry out a retrospective diagnosis in this way, if an acute phase sample is also available. It should be remembered, however, that many cases fail to develop a response, or that it may be delayed (Ch. LXXXVIII), and the test is of practically no value as a diagnostic measure.

CHAPTER LXXXIII

THE EPIDEMIOLOGY OF ACUTE ANTERIOR POLIOMYELITIS

GEOGRAPHICAL DISTRIBUTION

POLIOMYELITIS has an almost world-wide distribution as an endemic infection, and occurs in epidemic form chiefly in North America, Scandinavia, and Australia. During World War II, great interest was taken in serious outbreaks occurring in Malta, St. Helena, Mauritius, and S Africa. Another feature of interest was the much higher incidence of the disease in U. S. and British troops in India and the Middle East than at home stations It is being increasingly recognized that poliomyelitis occurs in tropical and subtropical countries as an endemic infection, although probably paralytic cases are less common in these warmer lands than in America, Scandinavia, and Australia. Certain general reviews on epidemiology may be consulted by those interested in this question (Dale, 1928[1], League of Nations, 1930, 1932, 1934, 1935, International Committee, 1932).

Particularly valuable information on epidemiology, which has been made much use of, was afforded by the *UNRRA Bulletin of Communicable Diseases*. The *Weekly Epidemiological Record* of the League of Nations and United Nations is also most valuable.

North America

Poliomyelitis has been endemic in Canada and the United States since the beginning of the century and presents a considerable problem Cases were seen in 1907, and it was thought that the infection was imported by European immigrants (Flexner, 1910, Fischer, 1917)

An average case rate in the United States is between 5 and 10 per 100,000 with [illegible] ie incidence [illegible] 1930–1945 [illegible] 1943, 1944, he states that in 1944 the rate was 14 per 100,000 (over 19,000 cases), a figure considerably above that of any preceding year, except 1916. In 1945 there were over 13,500 cases (Dauer, 1946) 1946 was also an epidemic year, and Dauer (1947) recorded 25,191 cases A feature of the disease in the United States has been the [illegible] less severely involved, since [illegible] canvass, found that 5.7 per [illegible] e, 3 0 per 1000 had residual paralysis

In Canada the annual incidence is usually around 3.0 per 100,000 In 1946 there were 2,500 cases

The following table gives some of the references to the main individual outbreaks of poliomyelitis in recent years In addition, the annual papers of Dauer give detailed information on the incidence of the disease in various states (1939, 1940, 1941, 1942, 1943, 1944, 1945, 1946, 1947, see also Davis, Weber, and Arey, 1941, Howitt, Buss and Shaffrath, 1942)

[1] References are appended at the conclusion of Ch LXXXVIII, p. 1026 et seq

Central and South America

Outbreaks have been recorded in the last 15 years in *Argentine* (*Bol Of San Pan*, 1943, Bustamente, 1944, Maggi, 1945), *Brazil* (Parreiras, 1939–40), *Chile, Colombia, Costa Rica* (Montes de Oca, 1941, Nunez, 1945), *Cuba* (Beguez César, 1942), *Ecuador, El Salvador* (Allwood-Paredes, 1944), *Mexico* (Stuck and Loiselle, 1943), Nicaragua, Panama (Taylor, 1944), *Paraguay, Peru, Puerto Rico, Uruguay, Venezuela* (Arcila and Requena, 1938).

West Indies

The disease is endemic in Barbadoes, Jamaica, Tobago, and Trinidad

Great Britain and Eire

In Great Britain the disease is endemic and the average annual number of poliomyelitis and polioencephalitis cases is not more than about 1000 Outbreaks have occurred from time to time, as shown in Table 39

A number of small outbreaks has been recorded of recent years in Eire (Musgrave, 1942, Deeny and McCormack, 1946).

1945	In a camp	Conybeare (1946)

In addition readers may consult the following papers *Lancet* (1937), Kelleher (1940)

The disease was very prevalent in 1947, the highest incidence for many years (about 18 cases per 100,000)

Scandinavia and the Arctic Regions

Poliomyelitis first made its appearance as an epidemic disease in 1905 (Wickman, 1907 Harbitz and Scheel, 1907 *a*, *b*) Numerous cases occured in all parts of Scandinavia at this *time*, *and in* Sweden *in 1905* the case rate was 22 per 100,000. The disease was quiescent from 1907–1911, but flared up again in 1911–1913.

Articles discussing the epidemiology of poliomyelitis in Scandinavia are those of Wernstedt (*1924*); Nissen (*1935*, *1936*), Wennerberg (*1035*); Wulff (*1936*); and Gard (1937, 1938)

In *Denmark* there were epidemics in 1920, 1924–5, 1929, in 1933–4 the case rate in a very *severe outbreak* was 126 per 100,000 (Jensen, 1934–5), in 1937 (Henningsen, 1939, Rasch, 1939, Henningsen and Rasch, 1940); *1942* and 1944 were years of high incidence

In Finland epidemics occured in 1919, 1930, 1931, 1934, 1935, 1940, 1944, and 1945.

In *Norway* there were epidemics in 1929, 1934, in *1936* there was a severe epidemic (Holst, 1938), in 1941, 1944, and 1945.

In *Sweden* epidemics occurred in 1923, 1924, 1928, 1929, 1930, 1932, 1934, 1935, 1936 (Kling, 1937, 1938 *a*), 1937–8 (*Bull. Off. int. Hyg. publ*, 1938, *30*, 2446), in 1943–1944 (*Dhunér*, *1944*), in 1945 Olin and Hemertz (1943) discuss the incidence from 1930–1939

Cases have been reported in *Greenland* (Hrolv, 1935, Høygaard, 1939); and *Iceland*, *especially in 1945*.

Europe

In France there was a considerable outbreak in the Bas-Rhin in 1930 (Levaditi, Schmutz, and Willemin, 1930), outbreaks occurred in 1943 and 1946 (see *J Amer. med. Ass*, 1947)

In *Germany*, from 1918 to 1924, cases occurred sporadically, but since that date there have been numerous epidemics, for instance, in 1932 there were approximately 4,000, and in 1934, 1,600 cases (see Mollers, 1936–7, Pohlen 1934, 1936 *b*; *British Medical Journal*, 1935). The disease was prevalent from 1936 to 1938 (Meier, 1938, *Reichsgesundheitsblatt*, 1938, Fey, 1939), epidemics occurred in 1939, 1941, and 1942 Austria has experienced various outbreaks (see Mayer, 1934, Khaum, 1937, Siegel, 1937, Zappert, 1937).

Outbreaks have occurred in the last 15 years in *Belgium*, especially in 1939 and 1945 (Lancet, *1945*), *Holland*, especially in 1943 and 1944, *Spain* (Albaladejo, 1936), *Italy* (Petragnani, 1937), *Roumania* (Marinesco, Manicatide, and Draganesco, *1929*), *Bulgaria*, *Hungary*, *Czechoslovakia* (Lancet, 1945), *Yugoslavia* (Djourichitch, 1937), Poland, U.S.S.R.

In *Switzerland*, the disease is becoming increasingly prevalent (*Bull Serv Féd. Hyg publ.*, 1936, Alder, 1937, Wieland, 1937, 1938, Exchaquet, 1938, Stahel, 1938, Abegg, 1942, Fanconi and Zellweger, 1942, Zellweger, 1945). Recent epidemics were those of 1941, 1942, and 1944

The Mediterranean Area

The disease is endemic on the *N African seaboard*, in Algeria, Morocco, and Tunis *In Egypt* the disease is endemic, and affects chiefly children under 5; adult natives are rarely attacked (Paul, Havens, and van Rooyen, *1944*)

In World War II, there was a high incidence of poliomyelitis of severe type in the *U.S*, *British, and Dominion Expeditionary Forces*, the incidence was about *10* times that in home commands (van Rooyen and Morgan, 1943, Paul, Havens, and van Rooyen, 1944, Illingworth, 1945, McAlpine, 1945, Caughey and Porteous, 1946, van Rooyen and Kirk, 1946)

In *Palestine* it is probable that the disease has been endemic since Biblical times The highest incidence is said to be in Jews, chiefly infants, Arabs are rarely attacked (Levy, 1937, Paul, Havens, and van Rooyen, 1944, Gruenfelder, *1946*)

Malta and Gozo. Poliomyelitis is endemic in Malta, and from *1921–1941* there were about 60 cases A severe epidemic began on November 15th, 1942 in Malta, on November 21st in Gozo, on the 27th Service personnel were attacked The epidemic ended *in* June, 1943 (Agius *et al*, 1945, Bernard, 1945, Bernstein, Clark, and Tunbridge, 1945, Debono, 1945, Seddon *et al*, 1945, Morana, 1945) Eighty per cent of the cases were aged under 5, and only 6 cases were over 10, the highest incidence was at 2 and 3 years, but many infants were attacked There were 426 civilian cases, and 57 in the Services Of 61 adults only 4 were Maltese The civilian fatality rate was 3 7 per cent and the service 19 3 per cent.

The etiology of the outbreak was obscure, but possible factors were overcrowding, physical fatigue, malnutrition resulting from the effects of aerial bombardment on an

unprecedented scale use of sewage to manure crops (Seddon *et al*; Morana). It was not possible to assess the relative part played by droplets or feces in the dissemination of the infection, and perhaps both channels were involved. Discussing the outbreak, van R[illegible] and Kirk (1946) concluded that fecal spread was the more [illegible] the strain of virus may have been [illegible] by service personnel. Neverthel[illegible] adult Maltese were immune.

Malta had a smaller outbre[illegible]ning in November, 1945, again affecting chiefly children under 5 (Kauntze, 1946).

Africa

Poliomyelitis appears to be endemic in the Belgian Congo (Vilen, 1942) and French Equatorial Africa (Ceccaldi, 1943). The disease occurs in West Africa, and affects chiefly children (Olitsky and Findlay, 1946), cases have occurred in Europeans, especially troops (Findlay, Anderson, and Haggie, 1946). The disease is common in the rainy season, as are amebiasis and hepatitis.

The disease has been described in N. Rhodesia (Gear and Rodger, 1946), and S. Rhodesia (Ratchken, 1944).

Of recent years, poliomyelitis has become more prevalent in the Union of South Africa, and numerous outbreaks have occurred (Gear, Yeo, and Mundel, 1945, Henson and Post, 1945, Kaplan, 1945, Turner, 1945, Gear, 1946, Gear and Mundel, 1946, Gear, Mundel, and Wilson, 1946, and the Report of the Union Department of Public Health, 1945).

Poliomyelitis was first noted in South Africa in 1917–18, when there was a severe outbreak. The incidence of the disease remained low until February, 1944, when there was an outbreak in Johannesburg. In September, 1944, Durban became involved, and the disease spread to other parts. The maximum incidence of the disease was in November and December, and for the year ended June 30, 1945 there were over 1,300 cases in the Union. It is possible that movements occasioned by the war introduced a virulent strain from the Middle East, and favored its spread.

St Helena

St Helena was visited by a severe outbreak during World War II (*Colonial Office Report*, 1945–6, Kauntze, 1946). There were 216 cases, 215 in Islanders and 1 in a European, between November 14th, 1945 and January 26th, 1946. Abortive and paralytic cases occurred in the proportion of 7:3. There were few cases under 5, and the majority was aged 10–25. Most deaths ocurred in the 15–20 age group. It appeared, therefore, that the virus was a "foreign" strain, perhaps introduced from South Africa, invading a population not immunized by previous exposure. A visit from a troopship appeared to be responsible. The state of nutrition was low at the time, owing to drought.

Mauritius

The disease is endemic in this island. In the first 5 months of 1945 there was a severe outbreak of 1,018 cases, the attack rate was 2.4 per 1,000 (McFarlan, 1946, McFarlan, Dick, and Seddon, 1946, Seddon, Hawes, and Raffray, 1946). Practically all the cases were under 10 and chiefly under 5. The evidence suggested spread of infection largely by healthy adults infected, probably in the nasopharynx, for a short time only. The age distribution suggested an epidemic "flare-up" of an endemic infection. There had been severe cyclone damage shortly before the outbreak.

India, the Pacific, and the East

The disease is endemic in India and affects chiefly children, adults being rarely involved, epidemics are unusual. During the second world war, from 1942–44, European and American troops had a considerably higher incidence of attack than in home bases, the disease was rare in British troops from 1938–41, and in Indian troops at all times (McAlpine, 1945–1946).

Sporadic cases occur in China (New, 1934, Scott, 1938, Yen and Hsu, 1941), Indo-China (Canet, 1936), Hawaii (Lee, 1941, Doolittle, 1943). Paul (1947 *a*) reports that despite the relative absence of epidemics in Japan, the average annual mortality rate is similar to that of the United States.

There was an outbreak in Malaya (in Singapore) in 1945–6, with approximately 85 cases, 60 being children under the age of 5, and 22 being Service personnel (Kauntze, 1946).

Australasia

Epidemics occurred in Australia in 1929, 1931, 1932, 1934. In 1937–8 over 2,000 cases occurred in Melbourne and Victoria (*Circular on Infantile Paralysis*, 1937, *Health*, 1937, 1938; *Health Bulletin*, 1937, 1938, Bull, 1937–8, *Med. J. Aust*, 1938; Burnet, 1940; Williams, 1940); Sydney was also involved (Hamilton, 1940), and New South Wales (Helms, 1941 *a*). There was an outbreak in 1945–6

New Zealand had an outbreak in 1936–7 (James, 1937; Watt, 1938).

AGE, SEX, AND RACIAL INCIDENCE

Age

Poliomyelitis outbreaks tend to show one of three common types of age incidence.

1. *With main attack on the preschool child.* Many poliomyelitis outbreaks have affected predominantly those under 5, hence the term "infantile" paralysis This type of incidence was usual in the cities and towns of the United States until 1918. Thus in the 1916 New York epidemic, and in Philadelphia, about 90 per cent of cases were under 5. More recently in the United States the incidence has changed (see below).

In the 1942–3 Malta outbreak, about 90 per cent. of cases were under 5 In the 1945 Mauritius epidemic the attack rate under 1 year was 4 per 1,000, at 1–5 it was 12 per 1,000, and then fell rapidly. In S Africa in 1944–5 the greatest incidence was in the 1–4 age group. These outbreaks, all, it should be noted, in warm climates, [illegible] an endemic infection This typc [illegible] such an occurrence. The sam [illegible] t and Japan in non-epidemic periods (see, e g., Paul, 1947 *a*). The virus is probably widespread in such *communities, and gives rise to immunity largely by subclinical* attack. Such a virus is presumably of high infectivity but of low paralysis-producing power (see Burnet, 1940) By the age of about 5, most of [illegible] the only susceptibles are the younges [illegible] incidence of any infection in infancy [illegible] of virus in the environment, which means that adults and older children are excreting it.

It is possible, however, that in poliomyelitis the acquisition of resistance with age is due to the development of physiological barrier mechanisms independent altogether of active immunity

It has been suggested that on first introduction to an area, poliomyelitis may also tend to give this type of age distribution Thus, in the 1943 El Salvador (S. America) outbreak, 90 per cent. of patients were under 5 (Allwood-Paredes, 1944).

Very young infants are not immune, and cases have been reported in newborn babies (Biermann and Piszczek, 1944, Frovig, 1947), and in one 4 *months old* (Hess, Levinson, and Hess, 1942)

2 *With main attack on the older child* A remarkable feature of urban poliomyelitis in the last 30 years in America, Australia, and Scandinavia has been the increasing tendency to involve the school as opposed to the preschool child In this way the age incidence resembles that of measles and diphtheria (Aycock, 1928, Burnet, 1940). Thus, in 1931 in New York, Laidlaw (1932) found twice as many cases over 5 as there were in 1916 In Philadelphia in 1932, 43 per cent were over 5, whereas in 1916 only 12 per cent. were over this age (Henry and Johnson, 1934). In Denmark in 1944, 53 per cent were over 15 (Horstmann, 1946), in 1934 there were 31 per cent over this age, and in 1911–14 only 10 per cent were over 15 (Jensen, 1934–5) The same increase in the percentage of older children attacked has been noted in Australia (see, e g, Burnet, 1940, Helms, 1941 *a*), and Switzer-

land (Fanconi and Zellweger, 1942; Zellweger, 1945). The phenomenon cannot be explained by the falling birth rate (Stocks, 1936). Other authors have confirmed this increasing tendency to affect the older child (Nissen, 1936, Dauer, 1938, Payne, 1941, Donovan and Bowman, 1942 *b*, Sherman, 1944; Landsberg, 1945; Conway and Bigwood, 1946). Burnet (1940) points out that the age incidence of urban poliomyelitis now resembles that of rural poliomyelitis in an earlier period

As regards America, the position is not quite as simple as has been stated, for differences exist between the North and South For example, investigating the disease in Alabama, in the Southern States, Wenner (1946) found that children under 5 were 3 times as commonly attacked as those aged 5–10, whereas in Connecticut at the same period, the 5–10 group was attacked at least as frequently as those under 5.

In the 1945–6 St. Helena outbreak there were few cases under 5, the majority being aged 6–20. It was suggested, therefore, that the causal virus was introduced from outside the Colony, and invaded a susceptible population not immunized by previous exposure, the "under fives" being presumably less exposed to infection

It has been suggested that the explanation of this increasing attack on older children is largely improved hygiene, the young child now having less opportunity of acquiring infection (Fanconi and Zellweger, 1942). Burnet (1945 *b*) points out that the changed age incidence has been largely apparent in the more highly civilized countries where improved social technique has diminished the spread of intestinal and respiratory infections in general. He holds that there are no grounds for believing that children under 3 are not still just as susceptible to the paralytic type of infection as older children, the difference from 30 years ago must be due to their less frequent infection

We may provisionally state, therefore, that a high attack rate on the under fives is characteristic of areas with poor social hygiene where there are frequent opportunities for infection of these children It should be noted that recent outbreaks with main incidence on the under fives have been in warm climates A high attack rate on the school child is characteristic of areas with a better social hygiene, where infection occurs later in life.

3. *With main attack on adults* Adults are not commonly attacked, and it is presumed that this is due to resistance acquired in childhood For example, in the 1944 N Carolina outbreak only 6 per cent. of cases were over 20 (Stevick, 1946). A number of outbreaks has, however, been recorded where about a third of the cases has been over 15 years of age; in certain outbreaks in reputedly "virgin soil" the main incidence has been on young adults (International Committee, 1932; Høygaard, 1939).

During World War II, European troops in the Middle East and India showed a much higher incidence than in home bases, and the mortality rate was high. Presumably these men were exposed to a virus to which they had no immunity. An interesting feature was the approximately 5 times greater incidence in officers, this was noted in India and the various Mediterranean zones (McAlpine, 1945; van Rooyen and Kirk, 1946) A possible explanation was the often poorer standard of hygiene in officers' messes, further there was a greater tendency for these ranks to feed at hotels and cafés

Other outbreaks have involved service men in the U. S. A (Goldstein, Hammon, and Viets, 1946, Nicholson, 1946)

There is probably no upper limit of susceptibility, and cases have been reported in persons aged 68 (Fox, 1938), and 69 (Lee, 1941).

Sex

The disease has usually shown an increased incidence in males as compared to females The International Committee (1932) summarized the published data relative to some 36,000 cases and found the male female ratio was 1.3 1 (see also

Henningsen and Rasch, 1940; Donovan and Bowman, 1942 *b*, Collins, 1946). While this ratio holds for younger children, it has been stated that after 20 years of age there are more cases in females than males

Race

Although poliomyelitis probably occurs in all parts of the world, certain races seem to be less susceptible to paralytic infection than white people. Thus in the United States the reported incidence in white persons is 3–4 times that in colored (International Committee, 1932, Harmon, 1936; Taylor, 1944, Collins, 1946, Stevick, 1946). In S. Africa, Gear (1946) found Europeans to be 10 times more susceptible than Africans

In Hawaii a higher incidence has been reported in Caucasian and Hawaiian groups than in Filipinos, Chinese, and Japanese (Lee, 1941, Doolittle, 1943).

The varying susceptibility of different races may sometimes, at any rate, be partly explicable by the nature of their work, or social status. Thus in the 1945 Mauritius outbreak, the Chinese showed a higher incidence, but probably because being largely shopkeepers they had more frequent contacts outside their families (McFarlan, 1946, McFarlan, Dick, and Seddon, 1946).

In other cases an apparent varying susceptibility in different races may be explained in terms of immunity. Thus in the Malta outbreak, cases occurred in British service personnel, but not in Maltese troops serving alongside Elsewhere in the Middle East, cases occurred in troops but not commonly in adult natives. The same situation was observed in India In these areas latent immunization protected the adults against the local strains of virus

It would seem then, that differences in racial susceptibility may be partly inherent, partly dependent on opportunities of contracting infection, and partly dependent on previous immunization

RELATIVE DISTRIBUTION OF CASES IN URBAN AND RURAL AREAS

Many observers have referred to a higher incidence in country districts than in towns and cities (Wickman, 1907, Lavinder, Freeman, and Frost, 1918, Levaditi, Schmutz, and Willemin, 1930, *International Committee*, 1932, Nissen, 1935, Canet, 1936, Lumsden, 1936, Root, 1936, Wulff, 1936, Petersen, 1941, Olin and Heinertz, 1943, Paul, 1947 *b*) It has been suggested that this is because resistance follows immunization by latent infection, which infection is naturally more prevalent in areas with the denser populations, than in rural areas where human contacts are less. Further, there is a tendency for a different age incidence in rural areas as compared to towns In rural areas, where immunization is less, one might expect the disease to attack persons of a somewhat older age than in towns, where the main susceptibles would be young people Gard (1938), in Sweden, found that in country districts most of the cases were aged 15–30, while in towns they were chiefly under 5 Paul (1947 *b*), investigating an outbreak in New York State and Pennsylvania in 1944, found that in the rural areas the older age groups had a higher incidence than was the case in urban districts This feature was not, however, noted in the 1937–8 Victorian epidemic (Burnet, 1940) In the 1945 Mauritius outbreak, there was a lower incidence in town dwellers at all ages, which suggested that the immunity in these persons was acquired earlier in life

SEASONAL DISTRIBUTION

The tendency for cases to occur predominantly in the summer and autumn in the northern hemisphere, and in the first 4 months of the year in the southern hemisphere has been recognized for a considerable time In the United States the median date of the peak week of notifications centers round August 15th in the South and September 12th in the North and West (Collins, 1946, see also Aycock,

1929) Quite a number of outbreaks has been reported as continuing into the colder months, and the report of the International Committee (1932) mentions approximately 40 such outbreaks. The 1933–4 Danish epidemic, for instance, showed a number of cases occurring in the early winter, and such was the experience of Wennerberg in Gothenburg (1935), the 1938 British epidemic also lasted into the winter (*Brit. med. J*, 1938), epidemics arising *de novo* in the winter are very unusual (see International Committee, 1932, McGugan, 1939) Dauer (1941) reports that when there is an increased prevalence in the late autumn or early winter, especially in a localized area, a more widespread epidemic is likely to follow in the summer.

Gard (1938) has stressed the rôle of certain meteorological factors in Swedish outbreaks. Thus, he found that an epidemic ceased when the temperature fell to 0 C., only to flare up again in March when the reading began to rise He also found that poliomyelitis epidemics consisted of small waves, and that the peak in each wave was preceded by an increase of rainfall, usually 14 to 20 days before (1937, 1938) Further information on the possible effect of meteorological conditions on the incidence of poliomyelitis would be of interest. For example, the study of saturation deficiency might throw some light on the importance of droplet infection

Neegaard (1942) has noted a rapid increase of cases in periods of weather apparently favorable. It may be that susceptibility is in some way increased in the autumn months (see Muller, 1945)

THE ECOLOGY OF POLIOMYELITIS

Of recent years it has become possible to visualize the essential biological character of poliomyelitis as an ecological problem. Thus Muller (1941) postulates a widespread distribution of the virus in epidemic periods Many persons are infected, and the virus reaches the CNS In some cases no significant symptoms result, while in others there are signs of abortive poliomyelitis In others, owing to some impairment of the relationship between the virus and the host, paralysis develops

Gard (1943 *b*), however, suggests that the course of infection resembles that in Theiler's disease, in that the virus multiplies in the intestine, and only exceptionally invades the nervous system

Paralysis may be regarded as an unfortunate complication from the point of view of the host, but of no ecological significance to the parasite (Burnet, 1945 *b*, Kendall, 1945).

Burnet (1945 *a*, *b*) has given much thought to this matter, and has formulated the following conception The virus is essentially a low-grade parasite of the pharynx, tonsils, and small intestine of children In nonepidemic times it is usually passed by fecal contamination and causes subclinical infection The virus survives as a species because it can be readily implanted in the pharynx and intestine of children, is excreted in feces, and is relatively resistant to destructive influences. Epidemic strains are endowed with the property of more readily causing paralysis, and have a greater potentiality for spread by the respiratory tract These strains may be regarded as biologically irrelevant mutations to a more invasive type However, the term "invasive" is relative, and the incidence of paralysis depends on unknown factors in the host

Burnet suggests that the virus has developed new biological potentialities in the 20th century Perhaps the virus evolved primarily as a parasite of the intestine of small rodents A chance mutant may have found its way to a human being by food contaminated with rodent feces, and produced disease At first, perhaps, the disease spread only from rodent to man, but eventually a variant arose which spread from man to man by the intestine or pharynx.

It is possible that a strain of low invasiveness growing in the epithelium of the gut would "blockade" the cells against a more invasive strain (Evans and Green, 1947)

ORIGIN OF EPIDEMICS AND OUTBREAKS

Poliomyelitis is endemic in many parts of the world, perhaps in almost all. From time to time epidemics occur, for reasons that are quite obscure. It is commonly believed that in areas where the disease is endemic most persons acquire immunity, chiefly by subclinical infection, fairly early in life The chief incidence is, therefore, on the under fives, and it may be postulated that epidemics occur when sufficient numbers of susceptibles have accumulated In certain parts of the world, owing to a higher standard of social hygiene, the attack is postponed to a later age

Epidemics may be precipitated by various causes. Thus in Malta there had been a long period of privation and hardship resulting from aerial bombardment, an additional factor was the recent introduction of human manure as a fertilizer. In Mauritius, cyclone damage occurred prior to the outbreak, and increased the overcrowding, a high incidence of intestinal infections was noted before the outbreak. Climate seems to play an important part. The rôle of such factors is probably to facilitate transfer of the causal agent and thus increase its virulence by passage.

According to this view, the causal agent of an outbreak is essentially the same as the endemic strain in antigenic structure, very likely some variant has developed which is endowed with properties that make it readily transmissible and of enhanced virulence (Burnet, 1945 *b*) "Foreign" adults entering such endemic areas may be susceptible to infection This point was demonstrated in the World War II, where the incidence of poliomyelitis in U. S. and British troops in the Middle East and India was about 10 times that in home commands.

Rather than a single strain being responsible, Aycock (1942 *c*) suggests that several may be in circulation and attain wide distribution at one time. A given outbreak may be precipitated by various factors, on a background of carriage of several strains. The absence of any simple method of "typing" strains of virus makes any such speculation difficult of general proof.

An alternative explanation for the origin of an epidemic is that the strain of virus may be imported Thus it was believed that the 1937–8 Australian epidemic was due to a strain from New Zealand The 1945–6 St. Helena outbreak was thought to have been caused by a strain introduced from S Africa, while the disease in this latter country in 1944–5 was held to be due to a strain imported from the Middle East or the U S A An outbreak in N Rhodesia was also attributed to introduction of a foreign strain In fact, the Middle East played a prominent part in the epidemiology of poliomyelitis in the World War II

Poliomyelitis has a pronounced seasonal incidence, and one has to consider how the infection is maintained in between outbreaks There is no evidence that virus is excreted by any considerable number of the community for long after the end of an epidemic (Wenner and Casey, 1943), and sewage in nonepidemic periods is usually virus-free It is probable that sporadic, chiefly abortive cases, occur throughout the year with sufficient frequency for the virus to be kept alive by passage in human beings There is no evidence, as yet, of an extrahuman reservoir of infection, for example, in a lower animal or arthropod It should be remembered, however, that the virus can probably survive outside the body in suitable conditions, for example, in water, for some months

In Buffalo in 1944, Smith *et al* (1945) inquired into the circumstances surrounding the development of the first 3 paralytic cases of the seasonal outbreak There was no evidence that these cases arose *de novo*, they were relatively late developments in a cycle in progress for about 3 months There was only an interval of 2 months between the last reported case in 1943, and the first probable case of abortive poliomyelitis in 1944 Owing to the difficulty in diagnosing abortive polio-

myelitis, they thought that this type of illness was probably occurring all the time between the 2 outbreaks.

Paul (1947 *b*) investigated an epidemic which evidently had its origin in a few paralytic cases in 2 townships in the winter of 1943–44 (October to May), 30 more cases appeared in the surrounding area in June-August, 1944; from June onward the epidemic quickly radiated outward.

Confirmation of the point that the infection may be present in a locality some weeks before the occurrence of the first case has been given by Gear and Rodger (1946), who in N Rhodesia found that persons visiting the locality in this period developed symptoms on return home.

Levaditi (1946) visualizes a widespread dispersal of virus at the onset of an epidemic, associated with an increasing neurotropism, and a changed susceptibility in the population The immune persons who become infected act as healthy carriers, the fully susceptible develop paralysis, the partly susceptible develop abortive infection

SOURCES AND MODES OF INFECTION

Infection with the virus of poliomyelitis can be contracted in many ways In some cases, the infection is autogenous, in others it is evidently contracted from food or milk; in many others, contact with a previous sufferer or close contact is responsible. In some instances healthy carriers are responsible. The rôle of arthropods, especially flies, has also been investigated, and must be considered seriously. The question arises in almost all cases whether the virus is transferred by the medium of feces or nasopharyngeal droplets.

Before discussing the various alternative methods of spread, it may be helpful to recapitulate very briefly what is known concerning the excretion of poliomyelitis virus from the human body.

Excretion of Poliomyelitis Virus by Cases and Contacts

This question is fully discussed on page 928 et seq., where it is shown that the essential points of importance in epidemiology are as follows

1 Virus is present in the nasopharynx of the case, whether abortive or paralytic, until about 3 days after onset A longer period of infectivity is unusual

2. Virus is present in the feces of the case, abortive or paralytic, for about 1–2 months

3 True convalescent carriers are very rare

4 Virus is widely distributed in the environment of abortive or paralytic cases It has been recovered most commonly from intimate contacts, such as members of the same family or playmates, and more usually from children than adults In these contacts, the stool remains infected longer than the nasopharynx

5. To summarize, the virus is known to be present in the nasopharynx, and for a longer time in the feces, of abortive and paralytic cases, and of intimate contacts—mainly children but including adults

Method of Transfer of Infection in Poliomyelitis

We have already pointed out that a study of the portal of entry of the virus may throw light on the method of transfer The result of modern histological observations is to emphasize the rarity of entry through the olfactory area and stress the importance of entry through the pharynx and small intestine The pharynx can be infected either by inhaled material passing downward, or by ingested material It is questionable, therefore, whether this work helps very much in deciding how the virus enters the body of the patient It is clear, however, that inhalation is not as common as ingestion.

Infected persons can give rise to infection in others by means of droplets of nasopharyngeal secretion or by feces.

Until a few years ago it was generally held that poliomyelitis was transmitted by droplets. The fact that the virus was present in the nasopharynx, and that nasopharyngeal symptoms were common in the prodromal phase were powerful arguments, at that time it was not realized that virus was also present in the feces. In certain recent outbreaks, experienced workers, after weighing the evidence, have concluded that droplet infection was the most likely explanation. This opinion was reached by those studying the 1937–8 Australia, the 1942–3 Malta, and the 1945 Mauritius outbreaks.

There have always been difficulties in accepting the droplet theory. For example, the seasonal incidence is unlike that of other droplet infections. Institutional and school outbreaks have always been unusual—a marked contrast to the state of affairs with influenza or measles.

In the last 10 years or so, evidence has increased that poliomyelitis is more usually spread by fecal material. In some cases, the fecal material may be ingested with food contaminated by flies, or by the washing of fruit and vegetables in sewage-polluted water, water supplies may be infected. This type of spread probably operates commonly in the subtropics and tropics, although it is unlikely that public water supplies are often concerned. Perhaps more usually the fecal matter is transferred by actual contact with the hands of the excreter, or by fomites such as soap and towels. It has been shown that the virus is usually spread to close familial contacts and playmates. Fairly prolonged and direct contact is necessary for the transmission of infection. The position would seem to be analogous to the transfer of dysentery bacilli, e.g., Sonne's bacillus. The seasonal incidence is certainly more in favor of an intestinal than a respiratory infection. It has been held that the rapidity of spread in certain outbreaks, e.g., in Malta in 1942–3, is against the fecal method of transfer, but the behavior of Sonne dysentery in recent years has been somewhat similar.

Burnet (1945 *b*) has suggested that in nonepidemic periods the virus is transmitted chiefly by fecal contamination. In epidemic periods, however, it is more usually spread by droplets.

Autogenous Infection

In a small percentage of cases, infection is precipitated by various factors (see page 919, of which tonsillectomy is the best ... esumed that the ... invades it shortly ... stools of norma ... likely that autogenous infection operates at all commonly.

Gard (1943 *a*), who has isolated a noninfective "intestinal protein" from the feces of healthy men and mice, suggests that this is a virus normally inhabiting the gut. It may be an invader of intestinal micro-organisms rather than the human or mouse body cells. Virus is continually absorbed and deposited in the lymph glands, where it is gradually destroyed. Th ... is is not neurotropic and normally ... strated to be pathogenic on ex ... under certain conditions, neurotropic variants develop. In mice, this may occur at weaning, in man climatic factors may be responsible. According to this view, poliomyelitis is in a sense an autogenous infection, although exogenous factors may precipitate an attack.

The Acute Case

The case of poliomyelitis, abortive or paralytic, excretes the virus in the stool for some weeks, and virus is also present in the nasopharynx for some days. Evidently, therefore, such persons may infect others. Careful epidemiological inquiries have shown that the patient is probably infectious for 4–5 days before, to 4–5 days after, the onset of symptoms (Aycock and Kessel, 1943). Casey (1942 *a*, *b*) found

the period to be 3 days before and after. The nonparalytic case is particularly dangerous, as he is probably not confined to bed The potential infectivity of the acute case has for long been recognized, but in the past it was not the general experience that these persons were responsible for spreading the infection to any considerable extent. For example, the International Committee (1932) stated that the lack of obvious connection between cases was "one of the striking and constant features of the epidemiology." Even 20–30 years ago, however, contact between cases was demonstrated in a number of outbreaks (see International Committee).

Of recent years the evidence has become increasingly strong that the source of infection frequently can be traced to fairly intimate contact with a previous case, abortive or paralytic, in the infectious period. It is generally believed that the young child, under 5, is more infective than the older child

Epidemiological inquiries have shown that a case has often played with a child in the infectious period Numerous workers have supported this concept of transmission of infection by close personal association with sufferers (Nicoll, 1917, Bingold, 1936, Langmuir, 1942, Burnet, 1940, 1945 *b*, Anderson, 1946; Gear and Rodger, 1946).

In the 1937–8 Victoria epidemic infection was thought to arise in this way in the bulk of cases. The hospital outpatient department was believed to be a common disseminating center. It was concluded that child contact was the main method of spread, and that adults were seldom involved (Bull, 1937–8)

Important observations were made in a rural outbreak in Alabama in 1941 by Casey (1942 *a*, *b*) He found that during the 3 days before the onset of symptoms, 81/101 cases had prolonged direct contact with a patient suffering from an illness compatible with poliomyelitis He found that human travel was the essential factor. The transmitters of the infection were almost all children under 15, mostly under 4 When the average distance (by air) of the places of contact for each 12 day period of the epidemic was calculated, there was evidence of a radial spread of infection at the rate of about 1 mile per 10–11 days (Casey, 1945)

In an epidemic in New York State and Pennsylvania in 1944, Paul (1947 *b*) showed that the spread of infection was outward from a central focus, traveling approximately 0.5 mile a day

From the days of Wickman, it has been known that poliomyelitis tends to spread along routes of travel, the spread being essentially determined by human intercourse

Langmuir (1942) made a survey of each home within 2 miles radius of 3 affected families The stools of 4/8 adults, and 16/19 children who were intimate contacts were found to be positive

An interesting investigation was made in urban Chicago by Casey, Fishbein, and Bundesen (1945). They made a census of all persons under 25 in an area within one block of a case, and made a comparison with a control area in a distant part of the city Of 66 persons in contact with poliomyelitis cases during the infectious period, 37 developed illnesses 6–15 days later that were compatible with a diagnosis of poliomyelitis, 24 persons were definitely diagnosed Later Casey *et al.* (1947) studied 22 contacts of cases, and found that 14 developed fever, presumably due to poliomyelitis, within 5–25 days of exposure

Pearson *et al* (1945) investigated the distribution of poliomyelitis virus in stools at Fort Worth They found virus in familial contacts very commonly, much less commonly in nonfamilial contacts, and only very rarely in noncontacts

In the Mauritius 1945 epidemic, 50 per cent of cases had direct or indirect contact with paralytic cases or with areas where the disease was occurring (McFarlan, 1940, McFarlan, Dick, and Seddon, 1946)

In outbreaks in the State of Utah in 1943 and 1945, Anderson (1946) found direct contact quite frequently

Further evidence supporting the spread of infection by close personal contact

with a case, is afforded by a study of familial and institutional outbreaks A very special instance is the contraction of poliomyelitis by nurses and laboratory workers (see below).

Familial infections.

Until recently, it was unusual to find more than 1 case per family. For example, in the 1916 New York epidemic, 44 children were exposed to infection in their homes, but only 6 3 per cent. developed symptoms (Neal, Du Bois, and Abrahamson, 1916–9). In Roumania it was found that only in 5 families out of 50 investigated could home contact be said to have given rise to a second case (Marinesco, Manicatide, and Draganesco, 1939). Investigating 400 cases in the Department of Bas-Rhin (Alsace) in 1930, Levaditi, Schmutz, and Willemin found no case of family infection.

More recently, contact in the home seems to have played a more important part, and numerous authors have recorded instances of 2, and much less commonly 3 ... Camps, 1940, Strangmann, 1940, Ay- c ... Gear and Mundel, 1946; Gear and I ... 1937–8 epidemic, 24 per cent. of the ε ... 1937–8). In some instances, doubtless, the 2 cases have been infected from the same source (Gard, 1938); in others it appears that the second case has been infected by the first.

Familial infections, as would be expected, are commoner when the exposed children are young than when they are over 10.

An interesting study of over 200 families in a town in which poliomyelitis was occurring was made by Paul, Salinger, and Trask (1932). In each of these families there had been at least one case of frank poliomyelitis The other susceptible children in the homes were found to show a high percentage of minor illnesses; thus, 39 per cent. of children from 1 to 4 years old and 32 per cent. from 5 to 9 had such attacks. Only 9 per cent. of children in homes where there had been no case of poliomyelitis showed similar illnesses. The evidence was most suggestive that the contacts were, in fact, suffering from nonparalytic attacks of poliomyelitis Somewhat similar studies were reported by Kramer and Aycock (1931–2).

A remarkable example of the wide distribution of virus that may occur in families and their contacts was afforded by the experience of Francis *et al.* (1942). Five children of one family developed bulbar paralysis after tonsillectomy. A 6th child, who was not operated upon, remained healthy, but excreted virus in the stool The virus was recovered from the stools of 2 cousins with whom 2 of the children had lived a month before An additional 4 cousins of another group with whom the children had lived later also carried virus, but showed no symptoms No virus was recovered from adult relatives, 3/28 playmates excreted the virus

Although there has been this increased tendency to familial cases in certain ... Malta in 1942–3 ... 945 ... mag- ... atly increased (Swartout and Frank, 1944).

Institutional outbreaks.

Although cases of poliomyelitis have frequently been nursed in general wards without any particular "barrier" precautions, institutional outbreaks have been rare. Outbreaks in various types of institution have, however, been recorded from time to time. Thus, numerous authors have described outbreaks in schools (Wickman, 1907; Halliday, 1930–1, Siegl, 1937, de Rudder and Peterson, 1938, Somerville, 1938, Wolter, 1938) In Great Britain, such outbreaks have been unusual and have seldom

involved more than a few boys, secondary cases have been few in number (*res. Counc. spec. Rep*, *No.* 227; Barber, 1938, Smith, 1939).

Outbreaks have also occurred in *children's homes* of various types (International Committee, 1932, Kramer, Gilliam, and Molner, 1939, Silverman, 1941; Gear, Yeo, and Mundel, 1945)

Camps and holiday homes have also been involved (Lagrange, 1939, Brown, Francis, and Pearson, 1945, Conybeare, 1946, Melnick, Horstmann, and Ward, 1946).

The evidence is that in these institutional outbreaks a large number of children and a lesser number of adult contacts become infected, and excrete the virus in the stool, a few develop abortive poliomyelitis, and still fewer paralytic symptoms. A few examples may be quoted

Virus was recovered from the stools of 5/6 boy contacts at a camp outbreak who must all have acquired their infection within 6 days of exposure, virus was recovered from the throats of 2/3 boys with positive stools (Brown, Francis, and Pearson, 1945)

In an outbreak of 5 cases in a home the virus was recovered from the stools of 3/12 healthy children, and from 2/3 who had a probable abortive attack; in all, 10/20 children harbored the virus at some time during a 30 day period (Kramer, Gilliam, and Molner, 1939) In this outbreak one nurse in close contact had virus in the stool

In a children's home where one case occurred, 2/7 healthy contacts excreted the virus in the feces (Gear, Yeo, and Mundel, 1945). In a boys' camp of 75 persons there were 4 cases of paralytic infection The virus was recovered from 1 pool of oropharyngeal washings, and 3 pools of stools. Some of the infective material derived from boys who had symptoms suggestive of an abortive attack, and some from boys who had no symptoms (Melnick, Horstmann, and Ward, 1946).

The number of cases of infection found in contacts depends partly on the thoroughness with which they are examined, both clinically and by laboratory means In one outbreak, Visser (1940) examined the CSF of all children and of the nursing staff, he found suspicious changes in all specimens Examination of spinal fluid protein has been used as a means of establishing the diagnosis in contacts who have had a suspicious illness (Andelman *et al.*, 1946)

Infection in laboratory workers and nurses.

Infection has occurred in laboratory workers handling infected cords, stools and other materials (Sabin and Ward, 1941 *a*, Gear and Rodger, 1946, Wenner and Paul, 1947). Wenner and Paul suggest that human material and freshly isolated strains are much more dangerous to work with than "stock" virus, the danger to technicians undertaking the diagnosis of poliomyelitis by laboratory methods is not inconsiderable In our laboratory we insist on the wearing of protective gowns, masks, gloves, and boots Nurses only occasionally develop paralytic or abortive symptoms, although it is probable that a proportion becomes infected and excretes virus in the stool (International Committee, 1932, Gear and Rodger, 1946) An unusual occurrence was the 1934 California outbreak where 11 9 per cent. of hospital employees became infected (Kessel, Hoyt, and Fisk, 1934).

The Carrier

Convalescent carriers are known to be unusual, as the great majority of persons ceases excreting the virus in the stool by two months and in the nasopharyngeal secretion by a few days We can safely conclude that convalescent carriers play no significant part in the spread of poliomyelitis

We use the term "healthy carrier" to refer to persons who have contracted infection, usually by intimate exposure to an abortive or paralytic case, but who show no symptoms of invasion Contacts so exposed who develop symptoms are

sidered under the heading of "The Acute Case," above. Some of these carriers may have had an illness of infection, but no further evidence of invasion of the tissues (Conybeare, 1946). Healthy carriers excrete the virus in the feces for a period similar to that in the acute case, and it can also be found in the nasopharynx. Another type of carrier is the "incubating" or "precocious" carrier. Such a person harbors the virus in feces or nasopharynx several days before the onset of symptoms. In one instance a boy with a positive stool, who later developed the disease, infected 7 contacts in the incubation period (Gear and Mundel, 1946).

In towns and cities each household is daily in contact with the outside world, and it is difficult, therefore, to implicate a carrier. Evidence confirming the rôle of carriers has been obtained, however, by certain workers who have studied the epidemiology of the disease in isolated rural areas where human contacts outside the family are strictly limited, and in island communities. For example, in Sweden, Wickman showed that carriers were responsible for infecting cases on isolated farms. Alder (1937) in Switzerland traced infection to the visit of a carrier. James (1938) traced the introduction of poliomyelitis to an isolated island to the arrival of a ship from an infected area. In all probability the St. Helena outbreak was initiated by the arrival of a healthy carrier among service personnel.

Some workers suggest that the Malta 1942-3 outbreak was initiated by healthy carriers in the services arrived on the Island from the Middle East (Bernard, 1945, van Rooyen and Kirk, 1946).

Conybeare (1946) recorded an instance of poliomyelitis developing in the sister of a boy who had attended a camp where poliomyelitis infection occurred, the boy had no symptoms, and must have been a healthy carrier. Doctors and nurses on their rounds may unwittingly act as carriers of infection (Turner, 1945).

In the Texas 1943 outbreak, temporary carriers were blamed (Bohls and Irons, 1944-5). In S. Africa in 1944-5, cases usually had contacts with a village where poliomyelitis was prevalent, or with persons from such a district (Gear, 1946).

The Mauritius 1945 epidemic afforded evidence of spread of infection by carriers (McFarlan, 1946, McFarlan, Dick, and Seddon, 1946). They found that families with a case had more outside contacts, through school, or by adults working away from home, than families not affected. The percentage of adult males working away from home was significantly higher in those families with a case of poliomyelitis. The curve of incidence of paralysis was "peaked," with a rapid fall. The outbreak was "explosive" and suggested that the disease was one of short incubation and high infectivity in a susceptible population. It was suggested that there was a large carrier wave in adults who became infectious a few days after exposure. A week later there was the smaller wave of paralytic infections. This experience was such as strongly to incriminate healthy adult males as transient carriers. The distribution of cases was so diffuse as to suggest that infection was probably spread by droplets and not by feces.

Healthy carriers can cause infection by means of droplets or feces. As virus is present longer in the feces, and as prolonged contact is usually needed, it seems probable that infection is more usually passed in this way than by droplets.

Infection by Arthropods

Mosquitoes and biting flies.

Various points have been put forward on theoretical grounds to support the suggestion that poliomyelitis may be spread by mosquitoes: the sporadic nature of cases, the supposed rarity of direct contact and of [illegible]
in the [illegible]
(Roser [illegible]
that m[illegible] any part in the transmission of the disease, because virus is seldom present in the blood of the acute case.

Numerous experiments have failed to support the theory. Thus Rosenau and Brues (1913) fed large numbers of *Stomoxys calcitrans* on an infected monkey, and immediately after on a normal animal, the infection was transmitted, but only

point of view of

Clark, Fraser, and

Noguchi and Kudo

(1917) were unable to infect monkeys with *Culex pipiens* by feeding on infected water or monkeys. *Aedes aegypti* fed on an infected monkey did not transmit the infection to a normal animal, and no virus was recovered from the mosquitoes by monkey inoculation (Cornell and Davis, 1939) No evidence to incriminate mosquitoes was found in the 1944–5 S. African outbreaks (Gear, 1946)

Paul (1947 *a*) reports that Mitamura has found virus to survive in *Culex* and *Aedes* mosquitoes, infected by feeding, for about 3 weeks.

Lice, fleas, bedbugs.

Lice have been found incapable of transmitting the virus (Howard and Clark, 1912), as have fleas (Kling, Pettersson, and Wernstedt, 1912). Musgrave (1942) suggested that rats might be naturally infected with the virus, and rat fleas might transmit the infection to man. Howard and Clark (1912) found that in one instance virus was capable of surviving, and apparently multiplying for at least 7 days, infection being transmitted by the bite. Conway and Bigwood (1946) wondered whether cat fleas might act as vectors

Houseflies and blowflies.

The fact that virus can be found so regularly in feces raises the question of whether flies are concerned in the spread of the disease. In some outbreaks flies have been reported as unduly numerous in the neighborhood of cases, and some workers have been inclined to attribute a definite part to the fly in the spread of infection (Henson and Port, 1945, Deeny and McCormack, 1946, Gear, 1946)

Various workers have isolated poliomye

Toomey, Takacs, and Tischer (1941) isola
sewage infected stream

In searching for virus, pools of flies should be separated into species, ground, suspended in saline, lightly centrifuged, and the supernatant etherized and inoculated intracerebrally in susceptible monkeys, a gauze filtrate of the supernatant can be inoculated nasally or abdominally. Both blowflies (*Phormia regina*) and houseflies (*Musca domestica*) can carry virus The blowfly appears to be much the most important fly

Flies collected in nonepidemic periods have not been found infected (Trask and Paul, 1943, Trask, Paul, and Melnick, 1943)

Flies infected with virus from feces obviously may contaminate milk and foods intended for human consumption An important experimental observation in this connection is that of Ward, Melnick, and Horstmann (1945) who exposed food to fly contamination in the homes of cases in the first week. The food was then given to chimpanzees, who excreted virus in their stools An extensive outbreak in a naval training school was thought to be due to contamination of milk by flies that had access to feces (see p. 964)

Flies may contaminate by means of their feet. Further, the virus has been found in feces and vomit deposited by flies within a short time of an infected meal (Rendtorff and Francis, 1943) It is important to know how long infected flies may excrete virus Using the Lansing strain, and *Musca domestica*, Rendtorff and Francis (1943) recovered virus for up to 2 days after a single infected meal, but there was

no evidence of multiplication (see also Bang and Glaser, 1943). Important studies have been reported by Melnick and Penner (1947). They fed the stools of acute cases to the blowfly (*Phormia*). Virus was recovered from the body of the fly as late as 12–16 days after the meal, and from the excreta for 3 weeks. In contrast, when murine and Theiler's strains were fed to *Phormia*, *Phaenicia*, and *Sarcophaga*, the virus was recovered for 5 days only, behaving like inert carmine. It is not yet possible to say if virus multiplies in *Phormia*, but this seems a possibility.

All attempts to recover virus from adult flies developing from larvae infected by feeding were negative (Bang and Glaser, 1943). The important question of *whether virus can survive from season to season in flies* has not yet been answered.

Systematic studies of the fly population at New Haven (Connecticut) have been carried out by Power, Melnick, and Bishop (1943), and Power and Melnick (1945), who found that *Phaenicia sericata* was the dominant fly, representing 80–90 per cent of all trapped. Different species were found to be most numerous in different parts of the season. The peak of the fly incidence preceded the peak of the poliomyelitis epidemic by 4–5 weeks.

Sewage and Latrines

Numerous workers have succeeded in isolating virus from urban sewage in epidemic periods (Paul, Trask, and Culotta, 1939; Levaditi, 1940, Paul, Trask, and Gard, 1940, Weston, 1940, Paul and Trask, 1941, 1942; Kling *et al*, 1942 *a*, *b*; Trask and Paul, 1942 *a*, Gear, Mundel, and Wilson, 1946, Melnick, 1946 *a*, 1947).

Virus was detected in Stockholm sewage 3 months after the end of an epidemic, but not 9 months later (Kling *et al*, 1942 *a*, *b*). It was also found in Johannesburg 3 months after the last case (Mundel, Gear, and Wilson, 1946).

Other experiments conducted at the end of epidemics have proved negative (Paul, Trask, and Gard, 1940, Paul and Trask, 1942, Melnick, 1947)

Sediment from a positive sample stored at 4° C. retained its infectivity for at least 3 months, *suggesting that the virus can survive outside the body for some length of time* (Kling *et al.*, 1942 *a*, *b*).

Mundel, Gear, and Wilson (1946) investigating various stages in the process of purification, detected virus in raw sludge, settled sewage, humus tank effluent, but not in treated sludge or sand filter effluent, the humus tank effluent was used for irrigation. Experimental work has shown that activated sludge can destroy virus under certain conditions (Carlson and McKhann, 1943, Carlson, Ridenour, and McKhann, 1943)

Virus has been recovered from privies used by cases (Howitt, Buss, and Shaffrath, 1942).

Virus has been isolated fairly readily from sewage in epidemic periods usually in the late summer and autumn, and it would seem to be present in much larger amount than can be accounted for by the number of cases (see, e g., Melnick, 1947). A possible explanation is that it can proliferate (Kling *et al.*, 1942 *a*, *b*) There is, however, no evidence that virus can proliferate in association with cultures of various intestinal bacteria, or water or sewage protozoa (Brutsaert, Jungeblut, and Knox, 1946 *b*, Evans and Osterud, 1946) It is much more likely that the large amount of virus present is an expression of its wide distribution in the intestines of healthy contacts of cases, and of the frequency of unreported abortive cases. For example, Melnick (1947) suggested that approximately 6 per cent of the inhabitants of a particular area in New York City may have been fecal carriers

There is considerable significance in these reports of the presence of virus in sewage Infected sewage is a potential source of infection in several ways (1) by gaining access to water supplies, or streams, or lakes used for bathing; (2) by affording a source of infection for flies, (3) by being used for manuring land or cultivating vegetables, or, more crudely, as occurs in the Middle East, for washing fruit and vegetables. There are not as yet any definite reports incriminating sewage

as a source of infection, but certain suggestive observations have been made. Thus in Louisiana in 1928–39 it was noted that small towns where there was a water supply but no sewage disposal, had a higher incidence than rural areas where there were neither, or larger towns where there were both (Casey and Aymond, 1940 *a*, *b*). It was accordingly suggested that the practice of liquefying excreta without removal was a factor in determining incidence.

Prior to the 1942–3 Malta outbreak, human excreta had been used as manure—a common custom in the Middle East at all times. In Mauritius the sanitation was very poor and consisted chiefly of unscreened pit latrines. Irish observers have also attached some importance to privies as sources of infection (Deeny and McCormack, 1946).

Technique of Virus Isolation

The most sensitive of several methods appears to be the following (Melnick, 1947). 1–2 gallons of sewage are allowed to settle in the refrigerator. The supernatant is filtered through gauze, 800 c.c. is treated with 120 c.c. ether, corked and placed overnight in the refrigerator. The next morning to the aqueous phase are added 32 c.c. of normal monkey or horse serum (inactivated at 56° C. for 2 hours), followed by 320 gms. $(NH_4)_2SO_4$, stirring till dissolved. After centrifugation at 2000 r.p.m. for 20 minutes the sediment is resuspended in 20 c.c. distilled water, placed in a cellophane bag and dialyzed against cold running water for 4–6 hours. The dialysate is centrifuged at 4000 r.p.m. for 20 minutes and the supernatant then centrifuged at 39,000 r.p.m. for an hour. The gelatinous sediment is taken up in 1–2 c.c. of 10 per cent. normal monkey serum. Following centrifugation at 18,000 r.p.m. for 20 minutes, to remove aggregated material, the sample is ready for cerebral inoculation in rhesus monkeys.

Water Supplies

As virus occurs so commonly in feces and sewage it is quite possible for it to gain access to water supplies. Although earlier work of Kling and Levaditi (1913 *a*) did not incriminate water supplies, Kling (1928) later supported the theory that the disease could be spread by this means. He stated that the distribution of groups of cases was dependent on water supplies, and that the disease first broke out near the supply in the hills, cases occurring successively as the stream descended. Gard (1938) stressed the importance of increased rainfall, and mentioned a laborer who was alleged to have contracted the disease a few days after drinking water from a ditch.

More recently in western Connecticut, Paul and Trask (1941) also found that the distribution of cases followed a water course. In Alabama, Casey (1945) suggested that sewage polluted waters concentrated by drought were responsible for infection in many sporadic cases in adults. In Sweden, Spaak (1945) blamed infected water supplies for sporadic cases occurring in a small parish, when the water was inoculated in monkeys, suggestive changes were produced. By inoculation of cotton rats, Toomey, Takacs, and Weaver (1945) isolated a poliomyelitis-like agent from a polluted stream.

In the 1945 Mauritius outbreak it appeared possible that ice was responsible in one village out of the numerous areas involved (McFarlan, 1946, McFarlan, Dick, and Seddon, 1946).

There has been considerable discussion as to the amount of chlorine needed to destroy poliomyelitis virus in the presence of organic matter in water. Some workers have found that amounts of free chlorine even up to 50 p.p.m., i.e., much more than are used in public supplies, cannot be guaranteed to inactivate virus in the presence of organic matter in a reasonable period (Kempf and Soule, 1940 *b*, Kessel *et al.*, 1943, Trask, Melnick, and Wenner, 1945). Levaditi, Kling, and Lépine (1931) found that virus was inactivated by 4 gm. Cl_2 per liter in 24 hours in the presence of organic matter.

The observations of Ridenour and Ingols (1946) suggest that chlorine can be

used in amounts that will inactivate virus, and yet give a palatable water. They found in tests with samples infected with the Lansing strain of virus that a free chlorine residual of about 0.2 p.p.m. inactivated virus after 10 minutes, with contact for 30 minutes, 0.1 p.p.m. was enough. A complication is the fact that mixed residuals of chlorine and chloramine are usually present (see Lensen, Rhian, and Stebbins, *1946*, *1947*). They found (*1947*) that at pH 6.85–7.4 virus was inactivated after 10 minutes in all samples with residuals of free chlorine and chloramine, even with as little as 0.05 p.p.m. free chlorine. With increasing pH, virus appeared more resistant to chlorine.

The effect of combined aluminum hydroxide sedimentation and sand filtration on infected water has been studied by Kempf *et al.* (*1942*), who found that 1.16 and 1.5 c.c. of sediment per liter produced a noninfective inoculum.

Ozone appears to be capable of rapidly destroying poliomyelitis virus (Kessel *et al.*, 1943).

The following methods of purification were found to hold back the virus in laboratory tests: sand filtration, aeration; absorption to charcoal, alteration of pH, storage, alum precipitation (Carlson, Ridenour, and McKhann, 1942). The same workers found that ultraviolet light destroyed most of the virus under optimum conditions.

It has been found that virus remains viable in tap water at refrigerator temperature for 100 days (Carlson, Ridenour, and McKhann, *1942*).

It may be said that very few workers believe that water is a usual source of infection, although it may account for a few sporadic cases in country areas. Epidemiological inquiries in numerous outbreaks have consistently failed to incriminate water supplies. The evidence against poliomyelitis being a water-borne disease has been marshalled by Krumbiegel (*1944*) who draws attention to these points. (1) outbreaks bear no relation to individual supplies, (2) outbreaks are not "explosive", (3) there is no association with other evidence of pollution. Similar remarks have been made by Maxcy (*1943*).

Milk

A number of outbreaks has definitely been traced to milk (*International Committee*, 1932). Of these the best known in Great Britain is the 1926 Broadstairs epidemic (Aycock, 1927). In America that in Cortland (New York) recorded by Knapp, Godfrey, and Aycock (*1926*), and that in a Midwest college (Rosenow, *1932*) attracted *much interest. Goldstein, Hammon, and Viets* (*1946*) reported an outbreak among cadets at a naval training school. Within 8 days there were 18 cases of polioencephalitis, and 100 of abortive poliomyelitis. Flies were numerous, had access to feces, and probably infected milk. Dead flies were common in milk jugs. Horstmann (*1946*) has blamed milk on general grounds.

In the majority of outbreaks the onset has been explosive, the cases having consumed milk from one dairy. Infection of the bulk supplies is presumably by nasopharyngeal droplets or feces from a carrier or abortive case employed in handling the milk.

Although poliomyelitis occurs in the chief milk-drinking age groups, and the virus can survive in milk for some weeks (see p. 1002), it is unlikely that the disease is spread by this means except on rare occasions.

Food

The height of the curve of poliomyelitis incidence coincides with that of the harvest of perishable fruits and vegetables, it has been suggested, therefore, that these articles may harbor the virus (Toomey and August, *1933*, Gebhardt and McKay, *1946*). Barber (*1938*) observed 4 cases developing in a single house of a boarding school on the same day, and tentatively suggested that the source of infection was strawberries. From their experience of poliomyelitis and infective hepatitis

(which have certain epidemiological resemblances) in the Middle East, van Rooyen and Kirk (1946) strongly support the importance of uncooked food or vegetables. They state that the consumption of uncooked food and vegetables, however well washed, is an ever present danger in the Orient [illegible]
have been used from time immemorial [illegible]
is to wash vegetabl[illegible]
of the local [illegible]
and officers' [illegible]
ogaster (the fruit fly) in [illegible], 1947).

Scobey (1946) has sug[illegible] changes ascribed to the virus of poliomyelitis may be produced *under the influence* of hydrocyanic acid found in fruit and vegetables.

Extrahuman Sources

It is natural to inquire whether there is any evidence that poliomyelitis may be contracted from nonhuman sources. Lumsden (1942), for example, concluded that infection was spread by infected localities, rather than by human contacts. He blamed hosts such as rats, birds, fowls, and bovines, with fleas, flies, and mosquitoes as vectors

There is no evidence that rats, chickens, pigeons, or larger farm animals harbor poliomyelitis virus, or that ants or cockroaches are infected (Toomey, Takacs, and Tischer, 1943, Gordon, 1945 *b*, Pearson and Rendtorff, 1945 *a*, Pearson *et al*, 1945). Although others have found no evidence that dogs may be infected with virus, Gordon (1945 *b*) reports that the sera of 3/37 animals neutralized the Lansing strain Poliomyelitis virus cannot live or multiply in tomato plants (Toomey and Corum, 1943)

A certain amount of suspicion has been thrown on pigs, who may suffer from a paralytic infection known as Teschen disease (see Ch LXXXI) Histologically this condition is identical with poliomyelitis, and is apparently due to a filtrable virus The highest incidence is in winter The balance of opinion is in favor of the disease being unrelated to human poliomyelitis (Frauchiger and Hofmann, 1941, Gard, 1943 *a*)

There has been some suggestion that paralytic conditions of chickens may be transmissible to man Thus, Preston (1941) observed cases of poliomyelitis, on an isolated farm, who had had no contact with the outside world for several months. He suggested that the infection derived from paralyzed chickens and turkeys, the causal agent may have been transmitted by the chicken louse

The only extrahuman source to be seriously considered is that of rodents, for a number of viruses similar to poliomyelitis, especially Theiler's virus, infect these animals under natural conditions (see Ch. LXXXI) Some human poliomyelitis strains also infect rodents. It is evident, therefore, that poliomyelitis virus is not a unique agent affecting man only, but is closely related to agents producing disease in rodents It has been suggested that human poliomyelitis virus is probably originally derived from rodents (Burnet, 1945 *b*)

Jungeblut and Dalldorf (1943) isolated a rodent-pathogenic virus (MM) from the brain of a house mouse found dead in the home of a fatal case of human poliomyelitis, a somewhat similar virus was found in the brain stem of the human case

Later (1946) they isolated 2 strains falling into the murine poliomyelitis group from a number of house mice trapped in the New York area. These strains were not identical but were closely related Brown and Francis (1947 *a*) found that rat sera might neutralize rodent strains, but failed to isolate virus from rat tissue.

At present, it does not appear to us likely that rodents, or other extrahuman agencies mentioned above, need be seriously considered as a source of infection in poliomyelitis

Conclusions

Certain conclusions can be drawn from the mass of detail available on the subject of the method of spread of poliomyelitis.

1. Evidence is strong that many cases are infected by intimate personal contact with abortive or paralytic cases, or with close contacts of these cases, who may or may not develop symptoms. Child contact is more important than adult contact Feces or less probably droplets may be the actual means of transfer of virus.
2. Some cases are infected by healthy carriers
3. Other cases are definitely precipitated by tonsillectomy and other less well defined traumata, the infection being autogenous.
4. Certain outbreaks have been definitely shown to be due to infected food, such as milk. Unwashed fruit and vegetables are also of importance.
5. Flies may be vectors, and can transmit the virus from feces to food.

PERSONAL PROPHYLAXIS IN POLIOMYELITIS

Following nasal instillation of alum, picric acid, zinc sulfate, or other chemicals, monkeys become insusceptible to nasal applications of virus (see p 986) Field reports of the use of these chemicals in man have been unsatisfactory, probably chiefly because of the rarity with which virus invades by this route.

The United States Public Health Service in 1936 suggested for trial a nasal spray of equal parts of 1 per cent. picric acid and 1 per cent. sodium alum in saline, this was to be applied 3 to 4 times daily in alternate days, and thereafter once weekly Armstrong (1936 *b*) reported the results of a trial of ½ per cent. each of picric acid and sodium alum sulfate dissolved in normal saline. As cases occurred in persons so treated, the effectiveness of the instillations could not be asserted.

Following on Schultz and Gebhardt's (1937) work with monkeys, Peet, Echols, and Richter (1937) recommended zinc sulfate sprays (see also Pentecost, 1937, Abt and Abt, 1938, Hayden, 1938, Schultz, 1938; Shahinian *et al*, 1938, Smith, 1938) Myerson (1938) recommended a 1 per cent. aqueous solution of picric acid Zinc sulfate has been used in Australia (Gutteridge, 1938).

The zinc sulfate spray was given a thorough trial in the Toronto 1937 autumn epidemic (Pentecost, 1937, Tisdall *et al.*, 1937). All spraying was performed in the most efficient manner, but no preventive value was shown

GENERAL PREVENTIVE MEASURES

The safest practice is to assume that cases of poliomyelitis are infective by nasopharyngeal droplets and feces. Accordingly the measures to be followed are similar to those adopted in cases of known droplet-and known feces-spread disease. Numerous authors have discussed the measures to be adopted in the control of poliomyelitis (*Ministry of Health Memorandum 1936*, MacNalty, 1938, 1942, Smith, 1939, Deeny and MacCormack, 1946, Gear and Rodger, 1946, *Medical Officers of Schools Association*, 1946), and their recommendations are broadly as follows.

Notification is practiced in almost all countries, and nonparalytic cases should be as fully reported as paralytic cases It is certain that the figures of incidence published by various countries are too low, because of a failure to report a considerable proportion of nonparalytic cases In America, where the position is probably better than in many other countries, about 70–85 per cent of cases are reported (Collins, 1946). The diagnosis of nonparalytic poliomyelitis is difficult, the tendency is to make the diagnosis with more readiness in the families and contacts of cases, than in persons not known to be exposed A personal canvass of all child contacts will result in cases being detected that would otherwise be missed The question of the Kenny concept is of considerable importance here, for the inclusion of cases showing spasm will result in a considerable increase in notification

Nelson and Aycock (1944) came to the following conclusions on the accuracy

of reporting The lowest percentage of cases reported was in the smaller localities. Cases were less frequently reported in the "off season" than in August, when 90 per cent were reported Cases under 2 and over 16 were often not reported.

Isolation. Cases, either abortive or paralytic, are usually isolated ... s. It should be remembered, however ... e ... s

... ing the spread of t ... Rol

Child contacts, a high p ... are probably excreting virus in the stools, should be quarantined at home for 3 weeks, and thus kept from school and other child gatherings.

It is not usual ... siderable propo ... adult contact w ... close contact with ... other than his c

A ... who q ... for a f

At ... of quarantine the homes should be disinfected

Opinions on the effectiveness of isolat ... tacts are varied For exam ... Australian epidemic

Isolation of the family or community. In rural areas it may be possible to isolate affected families, and a few judicious words to neighbors will discourage visits to a possible source of infection. As regards villages, Gear and Rodger (1946) in N Rhodesia were able to ban visitors to the village affected, so that the chances of the infection spreading elsewhere were minimized

Day schools In rural areas, day schools may usefully be closed, and child contact thereby minimized

In urban areas it is doubtful whether school closure as a general measure is of any value The occurrence of several cases in a class would, however, suggest the advisability of closing this class, and quarantining the children at home, school absentees should be visited, as many may be suffering from abortive poliomyelitis (Payne, 1941)

Residential schools The advice of the Medical Officers of Schools Association (1946) is as follows. (1) If the parents wish to remove the child they can do so if he can be isolated in transit and at home for at least 3 weeks. (2) If secondary cases appear (this is unusual) it may be best to disperse the school for at least 3 weeks. (3) On the occurrence of the first case, the school should be quarantined and all outside games and other fixtures cancelled (4) Strenuous games should be minimized.

Congregation of children. During times of epidemic, gatherings of children of all ages should, as far as possible, be forbidden. Children should not visit cinemas, Sunday schools, meetings of clubs or organizations, or camps If contacts are not quarantined, then they certainly must be prevented from attending these gatherings.

Instruction of doctors and general public The health offic ... all practitioners, health visitors school ... The ... paral ... should ... opera ... out-of ... of personal hygi ... handwashings sh ...

Provision of diagnostic and hospital facilities. It may be as well for the health officer to arrange for the services of an appropriate number of consultants to aid practitioners in diagnosis Laboratory facilities may require to be augmented

Arrangements should be made for the appropriate treatment, usually in an orthopedic hospital, of paralyzed cases, as a therapeutic measure rather than as a means of limiting spread.

Water supplies For additional safety, unchlorinated supplies should be boiled, or otherwise sterilized, during times of epidemic prevalence.

Disposal of excreta. The urine, feces, soiled handkerchiefs and bed linen of cases and contacts should be sterilized, e.g., by carbolization. Where privies and latrines are used, feces must be rapidly and completely covered with earth.

Food. Every attempt should be made to prevent fly contamination of foodstuffs, it may be desirable to boil milk shortly before consumption. Antifly measures should be taken, especially where privies or latrines are used, although large scale experiments using DDT in epidemic areas in the United States have not given a definite answer regarding the value of such procedures (Melnick *et al*, 1947).

Utensils used in eating and cooking should be immersed in chlorinated water before being washed (Deeny and MacCormack).

Operations. No tonsillectomies, adenoidectomies, or teeth extractions should be carried out during a period of epidemic prevalence.

Fatigue. During epidemic periods, children should as far as possible not indulge in strenuous games or occupations.

Bathing Bathing in streams, lakes, or even in chlorinated water in baths should be forbidden, owing to the risk of ingesting feces- or droplet-contaminated water.

CHAPTER LXXXIV

INFECTION OF MONKEYS WITH THE VIRUS OF POLIOMYELITIS

Some Other Suggested Etiological Agents of Poliomyelitis

It is not proposed to dwell in any detail on the numerous theories propounded to explain the etiology of poliomyelitis This has not been considered necessary in view of the present almost universal acceptance of the etiological nature of the virus, but those desiring further information on earlier theories should consult the survey of the International Committee (1932)[1] Two of these theories only will be considered in any detail.

Rôle of streptococci.

As in other disorders in which a virus has been isolated, claims for the rôle of a cultivable coccus have been made, and streptococci have been isolated by a comparatively large number of workers (e g, Mathers, 1916, 1917, Nuzum, 1916, 1917 *a*, *b*, 1918, Nuzum and Herzog, 1916, Rosenow, 1917 *a*, *b*, 1918 *a*, *b*, 1925, 1926, 1928, 1929–30, 1931, 1932 and see below, Rosenow and Gray, 1918, Rosenow and Wheeler, 1918, Hektoen, Mathers, and Jackson, 1918, Wayson, 1918 *b*, Cooper, 1931 *a*, *b*, Coole, 1945)

The main facts elicited by such workers will be briefly summarized Alpha-hemolytic streptococci were isolated from the brain, nervous system, and other parts of the body The organisms were filtrable through Berkefeld filters, and growth could be obtained from the filtrates Anaerobic cultures yielded growths of organisms similar to the "globoid bodies" (see below) The organisms were pathogenic for rabbits and monkeys, and were said to produce a disease similar to human poliomyelitis Antisera obtained from the horse were used in treatment Experimentally, however, these streptococcal antisera behaved in the same way as normal horse sera, and were not able to neutralize the virus (Amoss and Eberson, 1918 *a*, *b*, see also Stewart and Haselbauer, 1928) Precipitin reactions with nasopharyngeal washings were positive in contacts and cases, as well as in a smaller percentage of persons in the infected locality These streptococci were often regarded as one stage in a life cycle, the poliomyelitis virus being held to be the other stage Filtrates of streptococci were not, however, identical with the virus (Richardson and Mellon, 1931–2) Whereas the virus resisted glycerol for several years, the streptococci did not survive much over one year (Long and Olitsky, 1928–9, Rhoads, 1929)

Of recent years, Rosenow has strongly supported the rôle of streptococci in the etiology of poliomyelitis (see, e g, 1937, 1938, 1939 *a*, *b*, *c*, 1940, 1941, 1942, 1943 *a*, *b*, *c*, *d*, 1944 *a*, *b*, *c*, 1945) His main observations are as follows

1 Specific *alpha* streptococci have been isolated from the nasopharynx, stools, and blood of human cases, from experimental animals, water, sewage, flies, and dust

2 The inciting agent of poliomyelitis is represented by interrelated phases of the streptococcus and virus The streptococcus plays the primary rôle in the causation of the disease, the occurrence of epidemics, and the acquisition of immunity The virus is the small filtrable, highly invasive but relatively nonantigenic phase of the streptococcus Pleomorphic diplococci can be found in filtrates of cultures of streptococci, and are considered to be forms of the virus The streptococcus and virus are two forms of the one agent, the streptococcus is not a passive invader, but a part of the infectious process generally attributed to the virus

3 The serum of poliomyelitis patients agglutinates the streptococci Streptococci are also agglutinated by monkey convalescent serum

4 Precipitation occurs between antistreptococcal serum and extracts of nasopharyngeal swabbings or serum of patients

5 A cutaneous reaction has been developed in diagnosis This reaction is elicited on injection of the supernatant of an autoclaved suspension of streptococci The reaction is

[1] References are appended at the conclusion of Ch LXXXVIII, p 1026 et seq

greatest in the early stages of the disease; it disappears gradually on recovery, and abruptly when antistreptococcal serum is given

6 The intracutaneous injection of a specific polysaccharide also elicits a reaction, which is slight at onset but increases in convalescence.

7 Hyperimmune (horse) antistreptococcal serum also gives a skin reaction in infected persons.

8 Filtrates of streptococcal cultures in a special egg medium produce a fatal result on nasal inoculation in mice.

9 Monkeys recovered from infection with streptococci are immune to the human disease. They can also be immunized against the virus by injections of streptococcal vaccines combined with streptococcal antisera.

10. Antigen-antibody reactions specifically related to the streptococcus were demonstrated in the skin and serum of rhesus monkeys during experimental poliomyelitis Injections of antistreptococcal serum caused the skin and serum reactions to become negative.

The reactivity of the skin and serum of monkeys was demonstrated in 4–24 hours after intracerebral injection of killed poliomyelitis and arthritis streptococci, it disappeared in 48 hours

11. Antistreptococcal serum is of benefit in treatment of the human disease

Many workers have noted that animals injected with streptococci develop purulent lesions without paresis or other evidences of poliomyelitic infection (see, e g, Bull, 1917, Smillie, 1918; Wayson, 1918 *b*; Long, Olitsky, and Stewart, 1928, Fairbrother, 1929). It is not generally believed that streptococci play any important part in the etiology of poliomyelitis.

Globoid bodies.

A number of authors reported that opalescence due to small spherical structures or "globoid bodies" could be noted in rich culture media (such as ascitic fluid with rabbit kidney), inoculated with cerebrospinal fluid or brain tissue, and incubated anaerobically (Flexner and Noguchi, 1913 *a, b;* Amoss, 1914, 1917, Flexner, Noguchi, and Amoss, 1915, Tsen, 1918, Krauspe, 1928, Long, Olitsky, and Rhoads, 1930).

Small colonies consisting of clumps of bodies could be found in semisolid ascitic agar These globoid bodies were filtrable and apparently, on occasions, induced poliomyelitis in monkeys even after considerable dilution Despite certain of these results which appeared suggestive, it is not generally believed at the present day that the globoid bodies can represent the virus of poliomyelitis Logrippo (1936) investigated the whole position, and the following are among his more important findings (*a*) the opalescence in culture media thought to be specific for virus growth can be obtained in the complete absence of virus, (*b*) micrococci also develop in these tubes without the presence of virus, (*c*) forms resembling globoid bodies, and consisting of tissue lipoids, can be produced by the establishment of an electric field in the medium

Both streptococci and globoid bodies are now almost universally acknowledged to be without significance in the etiology of poliomyelitis, which is held to be caused by a specific filtrable virus, whose properties will now be described

HISTORICAL INTRODUCTION

Landsteiner and Popper (1908, 1909) were the first workers to record successful transmission of the infection to monkeys This work was rapidly confirmed by Flexner and Lewis (1909 *a, b, c*), Knoepfelmacher (1909), Leiner and Wiesner (1909); Landsteiner and Levaditi (1909 *a, b*), and many others It at once became evident that the causal agent was a specific filtrable and noncultivable virus Since the early days, large numbers of strains of virus have been isolated in all parts of the world and many have been passaged continuously since the isolation without fundamental change of character No purpose [illegible] more than a few of the later isolations of virus (e g [illegible] Romer, 1912, McIntosh and Turnbull, 1913, A[illegible] Flexner, 1932; Brodie, 1934–5 *d*, Kessel, Hoyt, and Fisk, 1934, Trask and Paul, 1936, Kessel *et al.*, 1936–7, Howitt, 1937 *a*, Sawers, 1938). Many of the early workers injected the virus intraperitoneally, intracerebrally, or by both routes combined

It soon became evident that monkeys are susceptible to infection by almost every possible route.

THE STANDARDIZATION OF VIRUS INFECTIVITY

It is clearly necessary to attempt some sort of biological standardization, for example, analogous to the MLD of various toxins, in the case of the virus of poliomyelitis. This has been carried out by Brodie (see 1932 *a*, 1933 *b*) who has formulated a standard "m c p." (minimal completely paralyzing) dose of virus, this is the smallest quantity of virus-containing tissue which will produce a complete and rapid paralysis in a monkey weighing 2.5 to 4 kilos within 13 days after intracerebral inoculation Less than 1 m c p. dose may cause infection, but only after a prolonged incubation period. Conversely, large amounts of virus (e g, 1,000 m c p. doses) may produce paralysis in as short a time as 3½ to 5 days, but doses up to 80 m c p. do not cause infection in any shorter space of time than the normal 7 to 14 days (Brodie, 1933 *b*). Madsen and Jensen (1936) have made use of the m c p method of estimating virus infectivity in their preparation of a standard poliomyelitis antiserum (see p. 1023).

It has been shown that pooled cords, ground up and mixed with 50 per cent. glycerol, retain a constant infectivity for at least 12 months (Kramer, Schaeffer, and Park, 1934).

When using mouse-pathogenic strains, titers can be expressed on the basis of calculating 50 per cent mortality end points

DIFFERENCES IN INFECTIVITY OF STRAINS

It is not possible to isolate virus from all cases of poliomyelitis by monkey inoculation, and probably human strains vary in their ease of adaptation to this host (see, e g, Flexner and Amoss, 1924 *b*) Once established, strains may vary widely in their infectivity Thus, Kessel, Moore, and Pait (1946) titrated 4 strains intracerebrally in *M mulatta* and obtained the following titers MV and Le—1 10,000 McK—1/1,000, Ba—1 '100. These differences were probably inherent, and not associated with the number of passages Recently isolated strains show a high degree of infectivity on intradermal injection, while passage strains are less regularly infective by this route (Trask and Paul, 1938)

The MA strain has undergone fluctuations in virulence At first feebly pathogenic to monkeys, it later increased in virulence, and became virtually fixed for about 3 years Then it again became of diminished virulence (Flexner, Clark, and Amoss, 1914 *a*) After treatment with glycerol, its former virulence was restored (Flexner and Amoss, 1914 *a*) A somewhat similar loss of virulence was reported with the LP strain which had been passed since 1910 (Levaditi and Hornus, 1932)

SPECIES SUSCEPTIBLE TO THE VIRUS

The majority of investigators has used rhesus monkeys (*Macaca mulatta*) and found them satisfactory, but numerous other varieties are at least as, if not more, susceptible The chimpanzee (*Pan satyrus*) is markedly susceptible Cynomolgus (*M irus*) monkeys have been quite widely used, Burnet, Jackson, and Robertson (1939 *b*), in titration experiments, found cynomolgus and rhesus monkeys equally sensitive to a passage strain (MV), but when a fresh strain (Mar) was used, the cynomolgus monkeys were far more susceptible Howe and Bodian (1947 *b*) using cerebral inoculation, found rhesus and African green monkeys equally susceptible Cynocephalus, cercocebus, cercopithecus, *M nemestrinus*, and *Papio babuin* monkeys, have all been found susceptible

The following named species of monkey belonging to the cebus, cercocebus, cercopithecus, erythrocebus, macacus, and papio families are among those that have been found suitable in recent years, and can replace rhesus monkeys

Species of Monkey	*Reference*
Cebus capucina (S American ring-tail)	Melnick and Paul (1943) Melnick (1946 *b*)
Cercocebus fuliginosus	Schabel and Gordon (1947)
Cercocebus torquatus	Findlay, Anderson, and Haggie (1946)
Cercopithecus aethiops sabaeus *C. aethiops centralis* *C. aethiops pygerythrus* (vervet)	Trask and Paul (1941 *b*), Paul, Havens, and van Rooyen (1944), Finlayson and Wicht (1945), Gear, Yeo, and Mundel (1945), Melnick and Ward (1945), Melnick (1946 *b*)
	Findlay, Anderson, and Haggie (1946)
Cercopithecus cephus (African mustache)	Ceccaldi (1943); Melnick and Paul (1943), Melnick (1946 *b*)
Cercopithecus diana roloway	Findlay, Anderson, and Haggie (1946)
Cercopithecus griseoviridis (grivet)	Paul, Havens, and van Rooyen (1944)
Cercopithecus mona mona	Melnick (1946 *b*)
Cercopithecus nictitans	Ceccaldi (1943)
Erythrocebus patas (hussar)	Paul, Havens, and van Rooyen (1944), Findlay, Anderson, and Haggie (1946)
M mordax	Melnick (1946 *b*)
Papio hamadryas (Abyssinian baboon)	van Rooyen and Morgan (1943); Paul, Havens, and van Rooyen (1944)
Papio papio	Findlay, Anderson, and Haggie (1946), Schabel and Gordon (1947)

The spider monkey (*Ateles ater*) is not susceptible (Mackay and Schroeder, 1935–6), nor is the common marmoset (Grossman and Kramer, 1936–7)

FACTORS PREDISPOSING TO INFECTION

Following ligation of the carotids, monkeys are more susceptible to inoculation (Schwab, Woolpert, and Hudson, 1943) It has been suggested that hypoglycemia may be an important factor determining susceptibility Monkeys subjected to exhausting exercise in the incubation period develop severer paralysis than controls, chilling has the same effect (Levinson, Milzer, and Lewin, 1945) The incidence and severity of paralysis is significantly greater in monkeys inoculated in the summer (Moore *et al.*, 1942, Moore and Kessel, 1943, Levinson, Milzer, and Lewin, 1945) Trauma applied to the limbs in the incubation period does not influence the severity or location of paralysis (Levinson, Milzer, and Lewin, 1945)

The rôle of vitamins has been investigated It has been claimed that virus spreads more readily along nerves in vitamin D-deficient monkeys (Toomey, 1940 *a*), although the nerves of rachitic animals show no difference in their ability to absorb virus *in vitro* (Toomey, Tischer, and Takacs, 1942) However, Sabin *et al* (1941) found no evidence that the ability of virus to reach the CNS after sciatic inoculation depended on vitamin D nutrition Rhesus monkeys deficient in thiamine did not exhibit increased susceptibility (Clark *et al.*, 1945) Rhesus monkeys suffering from a chronic deficiency of folic acid showed an increased resistance to inoculation, those with an acute deficiency did not exhibit this resistance (Lichstein *et al*, 1946)

As regards the possible influence of endocrine factors, it has been found that uncastrated female rhesus monkeys given theelin nasally show a normal degree of susceptibility to intranasal infection (Schultz, 1941) Normal monkeys treated with stilbestrol showed no increased resistance, treated castrates, however, showed a

marked increase in resistance to nasal instillation (Curley and Aycock, 1946). Sexually immature monkeys develop a severer disease than older animals (Moore *et al*, 1942; Moore and Kessel, 1943).

ROUTES OF INFECTION WITH THE VIRUS

1. Intracerebral

Virus is usually inoculated with a ¾ inch needle into the cerebral hemisphere on one or other side. Bodian and Howe, however, recommend inoculation of 0.4 c.c. into both thalami. The skull is exposed, and a hole drilled ⅛ inch to either side of the midline, just caudal to the frontoparietal suture A 24 gauge 1 inch needle is used to inject (see Morgan, Howe, and Bodian, 1947).

This route is the most certain in its results (e g, Landsteiner and Levaditi, 1909 *b*, Flexner and Lewis, 1909 *a*, 1910 *d*, McIntosh and Turnbull, 1913). Paralysis usually develops after 7 to 10 days, but if this does not occur, the monkeys can be reinoculated, when an accelerated response takes place with the rapid development of the characteristic syndrome (Flexner, 1931 *a*). If monkey strains are inoculated together with autolyzed mouse brain, a fulminant infection is said to result (Milzer and Byrd, 1947).

After intracerebral injection, the virus increases locally for a short time (Jungeblut, 1930–1 *d*), but soon leaves the site of inoculation and spreads to other parts of the brain The paths taken by the virus, and the changes produced, have been studied in particular by Fairbrother and Hurst (1930), whose work will now be described

For the *first* 2 days there is some localized nerve cell destruction at the site of inoculation, the meninges over the cerebral hemispheres show an infiltration of the pia with lymphocytes

By the *3rd and 4th days* the homolateral thalamus has become involved, and sometimes the midbrain and pons, but never the cord.

By the *5th day* the cerebral cortex shows the following changes Meningitis is irregular in intensity and distribution, and is associated with perivascular infiltration of the superficial cortical vessels There are also deeper perivascular and more diffuse infiltrations, most marked on the inoculated side, and unassociated with any overlying meningitis, these deeper lesions are pronounced in the vicinity of the site of inoculation The homolateral globus pallidus, anterior perforated space, and amygdaloid nucleus all show perivascular infiltrations. The homolateral thalamus is severely involved and the contralateral to a lesser extent No definite chain of lesions can be demonstrated connecting the site of inoculation with the basal nuclei Nerve cell lesions are now evident in the stem and spinal cord, but are quite unassociated with interstitial or meningeal changes

By the *8th day* the changes have approached those described as characteristic of the declared disease with lesions widespread in the cord and brain stem and much severer than those noted on the 5th day (Hurst, 1929, see p 991). The lesions elsewhere in the central nervous system, on the other hand, have not increased much in severity

Fairbrother and Hurst conclude from their study that the spread of the virus is essentially axonal, and that the primary changes are those of nerve cell destruction, and are not meningeal or vascular In this assumption they have the support of Pette, Demme and Kornyey (1932), and Luhan (1937) Howe and Ecke (1937–8 *a*) have found definite evidence of the spread of virus by decussating paths, they injected monkeys in certain selected areas of the brain and studied the situations where paralysis first appeared Thus, after injection of the visual cortex, uncrossed paralysis developed in 50 per cent of cases, after injection of the premotor area, crossed paralysis developed in a little over 50 per cent of cases, and, finally, after injection of the motor area, crossed paralysis appeared in almost all monkeys They

concluded that these results were what would be expected if the virus spread to the cord via definite nerve tracts.

Bodian and Howe (1939) reported that, in the prodromal stages after intracerebral inoculation, the distribution of lesions suggested that the pathway from the motor cortex to the lower centers was via the globus pallidus, zona incerta, field of Forel, substantia nigra, and tegmentum of midbrain, and not by the [illegible] t cortical-spinal route.

[illegible]

of [illegible] [illegible] intracerebral [illegible] such animals, the characteristic histological changes, as well as the presence of the virus itself, can only be detected in the proximal segment of the cord. Although the main spread of virus thus seems to be axonal, Schaeffer and Muckenfuss (1938) showed that after intracerebral injection, virus enters the cerebrospinal fluid more readily if long needles are used, and the inoculum is large.

2. Intraspinal

The virus of poliomyelitis may be injected intraspinally or intracisternally, and this is a reliable route of infection (see, e.g., Flexner and Lewis, *1910 c*; Clark and Amoss, 1914, Hurst, 1932). After such intrathecal injection, the virus is demonstrable in the cerebrospinal fluid for at least 5 days, but is usually absent at the time of onset of paralysis (Clark and Amoss, 1914; Hurst, 1932). Howe and Peele (1939) found that infection developed on intrathecal injection only if there was pial injury

With regard to the exact route whereby the virus enters the central nervous system from the cerebrospinal fluid after intrathecal injection, there is some difference of opinion. On the one hand, Clark and Amoss hold that the virus first causes involvement of the pia-arachnoid, and then probably spreads in along the perivascular spaces to involve the parenchyma of the cord and brain.

Hurst, on the contrary, holds that the virus enters by the ependymal lining of the 4th ventricle. He did not find that the site of severest meningitis necessarily corresponded either to underlying parenchymal lesions or to the distribution of the virus, as would be expected if infection spread in from the meninges He found lesions typical of poliomyelitis in the vicinity of the 4th ventricle, in certain cases where the animals died rapidly, there was widespread necrosis of nerve cells in the pons and medulla, thus clearly suggesting that this area was the portal of entry. Entered through the 4th ventricle, the virus presumably spreads by nerve tracts to the cord and motor cortex, as Hurst regularly detected it there during the period of paralysis.

Animals can be infected by inoculation into the lumbar cord (Melnick, Horstmann, and Ward, 1945).

3. Intraneural

The sciatic and radial nerves of the monkey have been injected by various workers and infection found to result with some regularity, especially if the nerve is traumatized by the needle (e.g., Flexner and Lewis, 1909 *b*, 1910 *c*, Landsteiner and Levaditi, 1909 *b*, Leiner and Wiesner, 1910 *a*, Hurst, 1930, Toomey, 1934–5 *b*, *d*, Bodian and Howe, 1940 *a*, *b*, Sabin *et al*, 1941, Sabin and Ward, 1942 *a*, Howe and Bodian, 1942 *a*, Toomey and Takacs, 1942) The nearer the nerve injected to the central nervous system, the quicker is the onset of paralysis (Demme, 1930).

If large nerves are cut, and virus is injected intravenously, poliomyelitis may develop, the virus presumably enters the cut extremities, and spreads along the nerves to the central nervous system (Lennette and Hudson, 1936 *a*) Sabin and Ward (1942 *a*) studied the distribution of virus after sciatic inoculation They found none in the nasal secretion, olfactory bulbs, nasal mucosa, tonsils, salivary

glands, adrenals, superior cervical sympathetic ganglia, abdominal celiac ganglia, and small intestines. Virus was found only in the cord

Hurst (1930) carried out an extensive investigation into the pathogenesis of poliomyelitis following intrasciatic injection. He found that monkeys could be infected regularly if the needle point was moved about to traumatize the nerve. After such an injection he found the following course of events (1) The virus spreads centripetally rapidly, although if a section intervening between the site of inoculation and the central nervous is removed within 24 hours, no infection results. (2) Virus is first demonstrated in the lumbar cord, and paralysis appears first on the inoculated side (3) Next, virus is demonstrable in the leg area of the motor cortex, first contralaterally; later, a decussating mechanism comes into play, the virus being found homo [illegible]
the cervical cord and ir [illegible]
may contain virus, but [illegible]
similar studies in a later [illegible]
not demonstrable in the cerebrospinal fluid in the presymptomatic period.

As regards the histological features in monkeys injected by the sciatic route, a number of characteristic changes occurs. In the inoculated nerve itself there is an inflammatory reaction, but only at the site of inoculation, the bulk of the nerve [illegible]

[illegible] but soon spread to the opposite half, and upward to the thoracic and cervical portions, as well as the motor cortex During the spread of the lesions, it is possible to observe that nerve cell degeneration is the primary change, and that the meningeal reaction is only secondary Eventually, lesions typical of established poliomyelitis can be found at all levels of the cord and midbrain With regard to the rest of the central nervous system, there is a somewhat unevenly distributed meningitis over the hemispheres, probably caused by the actual presence of virus in the cerebrospinal fluid, this meningitis bears no relationship to cellular foci or perivascular infiltration in the subjacent tissue.

Toomey (1933–4 *a, c*) has suggested that, following sciatic injection, virus spreads to the central nervous system by the sympathetic nerves He carried out transection of the cord in the thoracic region, and then injected virus into the sciatic nerve Both virus and typical lesions were discovered later in the cervical cord

Howe and Bodian have carried out extensive studies on the pathogenesis of infection after sciatic inoculation (see 1942 *a* for a general presentation of their work). In these experiments they infected the nerve by cutting with sharp scissors, and moistening the central end with virus Symptoms develop in 4–6 days (Bodian and Howe, 1940 *a, b*, 1941 *b*)

1 It would not appear that virus actually multiplies in the nerve, and an infective dose can reach the CNS by a large number of fibers in contact for a short time, or fewer fibers in contact for a longer time (Bodian and Howe, 1941 *b*).

2 The rate of progression in the nerve is approximately 2.4 mms. per hour (Bodian and Howe, 1941 *c*)

3 This result is not altered by previous section or two nerve freezes peripheral to the point of inoculation, 2–6 weeks before the inoculation (Bodian and Howe, 1941 *b*)

4 Inoculation of the nerve, a few moments after freezing at a point central to the inoculation site, does not produce infection The momentary freezing causes degeneration of the nerve fibers peripheral to the point frozen, but does not interrupt the physical continuity Clearly, therefore, living fibers are necessary for the transmission of the virus (Bodian and Howe, 1941 *b*).

5. In other experiments, the nerve was frozen at a single point, and the fibers allowed to regenerate several centimeters into the peripheral segment. The peripheral segment was then cut and inoculated Infection resulted only if regeneration had proceeded for at least 2 months (Bodian and Howe, 1941 *b*).

6. In these experiments, the nerve fibers were successively interrupted by transection or freezing at 2–3 week intervals at least 3 times. Inoculation of the central stump, where the nerve fibers are anatomically intact, did not produce infection About 2 months after the last transection, inoculation of the central stump proved positive. Evidently, metabolic changes induced in neurons or axons during regeneration under these conditions, prevent infection of fibers which are intact as regards vascular supply, lymphatic connections, connective tissue sheaths, Schwann and myelin sheaths. It is, therefore, highly likely that it is the protoplasm of the axon that transmits the virus, but cannot do this in the presence of metabolic disturbances consequent upon regeneration (Bodian and Howe, 1941 *b*).

Bodian and Howe have thus shown conclusively that poliomyelitis virus, after inoculation of the sciatic nerve, spreads to the neurons in the CNS by the axon fibers.

4. Intra-ocular

Injection into the anterior chamber secures infection (e g, Landsteiner and Levaditi, 1909 *b*). Injections into the vitreous also yield positive results (Flexner and Amoss, 1914 *b*) Burnet, Jackson, and Robertson (1939 *a*) have shown that rhesus monkeys are susceptible to inoculation in the posterior chamber with the MV strain. Bilateral ptosis is the usual initial symptom The most intense changes are found in the midbrain, especially in the region of the oculomotor nuclei The virus probably trave

bodies and superior

nerves In experimer

tory changes in various parts of the brain stem, but the 3rd nerve nuclei were not visibly affected, these animals were susceptible to the MV strain and another strain Mar.

5. Intranasal Instillation

Intranasal instillation was employed by Flexner and Lewis (1910 *d*) and Leiner and Wiesner (1910 *a*), and has always proved popular. Pledgets of wool soaked in virus and inserted into the nostrils are also used It is frequently noted, however, that single applications may fail to "take," though repeated injections are more successful *Strains vary greatly in the readiness with which infection* develops Thus, using Aycock's strain, not over 50 per cent. were found to develop infection, while with Flexner's MV strain, 77 per cent. became infected (Schultz and Gebhardt, 1932–3) These workers increased the percentage of "takes" to 95 per cent. by washing the nasal passages with M/15 phosphate solution (pH 5) previous to the actual instillation. The value of this method has been confirmed (*Hudson, Lennette,* and Gordon, 1936, and others) Howe and Bodian (1942 *a*) recommend inoculation with a pipe cleaner The trauma caused by rubbing causes the infection to progress more rapidly. More recently these workers recommend suspending the anesthetized animal with head hanging over the edge of a table, and inoculating directly onto the olfactory area.

Another reason for occasional failure to infect was brought forward by Flexner and Amoss (1920), who showed that the nasal mucosa and secretions might destroy the virus, this poliocidal substance was unrelated to serum viricidal antibody.

Flexner ... central

nervous sys ... ro-

ducing an ... ny

difference in the result of intranasal inoculation according as to whether the monkeys were kept cold or warm

Distribution of virus after nasal instillation. Earlier workers showed that virus could still be demonstrated in the mucosa for up to 4 days after inoculation (Flexner and Amoss, 1920, Faber and Gebhardt, 1933). This question was studied by Sabin and Olitsky (1938), who found that virus disappeared in 4 hours or less from the mucosa, but could be found at 96 hours. They used a strain passaged by the nasal route, which may behave differently.

After inoculation, the virus ascends and can be demonstrated next in the olfactory bulbs, tracts, and lobes (Levaditi and Landsteiner, 1910 *d*, Flexner and Clark, 1912–13, Sabin and Olitsky, 1938). Virus does not ascend, apparently, to the central nervous system in immune monkeys (Sabin and Olitsky).

A careful estimation of the progress of the virus from the nasal mucosa to the cord and other parts of the central nervous system was carried out by Faber and Gebhardt (1932–3, 1933). (*a*) Three days after inoculation the virus could not be found in the homolateral olfactory bulb or elsewhere. However, later Sabin and Olitsky (1938) found virus in the olfactory bulbs 72 hours after instillation. (*b*) By the 4th day the homolateral bulb contained virus and (*c*) by the 5th day the contralateral bulb also. The virus was found elsewhere only in the left hypothalamus and medulla. (*d*) By the 6th day it was present in both thalami in addition. (*e*) By the 7th day it had reached the cervical and lumbar cords and spinal ganglia. The rapid spread of virus was also emphasized by Kramer and Parker (1932–3), and Schultz and Gebhardt (1939).

Faber (1936–7) carried out an experiment which threw further light on the progression of the virus through the nervous system He injected monkeys with trypan blue, and later carried out nasal instillation After 3 days, dilatation of blood vessels in the diencephalon was detected, after 6 days, blue staining (indicating vascular dilatation) occurred in the brain stem, gray matter of the cord, and also in areas in the precentral gyrus and hippocampus. This work clearly demonstrated that by 6 days the virus had reached the cord, leaving a trail of lesions In a later publication (1938), he reported on this work in greater detail In the 1st stage after intranasal inoculation, lesions were found in the olfactory bulbs, and there was fever In the 2nd stage there was a marked and severe reaction in the brain stem down to the medulla, and the secondary olfactory centers were implicated In the 3rd stage there was increased involvement of the medulla, and involvement of the cord was first noted In the later stages the lesions were localized in the cord—sometimes unilaterally Faber concluded that certain nerve cells must be capable of complete recovery, after transmitting the virus Distribution such as that just described can best be explained by postulating that the virus spreads by the olfactory neurons There is strong proof that this is the path, for it has been shown that following interference with the olfactory nerves, either by surgical division or by nasal instillation of chemicals, infection does not follow nasal inoculation Arrived at the brain, the path of spread is probably by the olfactory relays and formatio reticularis (Faber, 1933)

pre;
per
from these areas (viz, the olfactotegmental, hypothalamotegmental, and the periventricular bundle of Schutz) They found no evidence that the spinothalamic tract was a pathway of spread

Virus does not enter the lymph after nasal inoculation (Yoffey and Drinker, 1939)

The histology of the olfactory bulbs These delicate structures are easily torn off and lost in removal of the brain, thus accounting for the lack of information on their histology Sabin and Olitsky have studied this question thoroughly

(1936–7). Four days after intranasal inoculation, definite lesions are present in the bulb. The outer layer of fibers and the subjacent glomerular layer show infiltration with polymorphs and lymphocytes, there is advanced degenerative change present in many of the large mitral cells, with some neuronophagia. It was noted that although virus may be inoculated bilaterally, only one bulb may show these lesions. If the animal fails to succumb, the lesions probably heal quickly. No such changes develop in the bulbs of immune monkeys, nor of normal monkeys inoculated by routes other than the nasal.

Accelerated response after nasal instillation. Generally speaking, paralysis develops 7 to 10 days after inoculation. Should this fail to eventuate, the instillation may be repeated, when fever and paralysis promptly develop (Flexner, 1933 *a*, Elford, Galloway, and Perdrau, 1935). It has been suggested that Draper's dromedary type of the human
due to reinfection, with
pleocytosis and globulin
nasal inoculation, even in immune animals.

6. Inhalation

Rhesus and cynomolgus monkeys can be readily infected by exposure to droplet nuclei of atomized virus in a suitable chamber (Faber and Silverberg, 1941, 1942, Faber, Silverberg, and Dong, 1943 *a*, 1944). Infection is usually contracted by the olfactory route Further experiments were performed where in some animals the olfactory mucosa was treated with zinc sulfate, to exclude transmission of virus by the olfactory pathway. Infection developed in a few of those treated The symptoms and histological examination suggested that virus had entered by the lower respiratory mucosa in the rhesus monkeys, and by the oropharynx in the cynomolgus monkey. In cynomolgus monkeys, the usual route followed was by the afferent fibers of the trigeminal to the gasserian ganglion, and thence to its central connections in the pons and medulla, the 9th and 10th nerves might also be concerned Less commonly, the pathway consisted of the sympathetic fibers of the nose or nasopharynx into the cervical sympathetic ganglia, and thence to the upper thoracic cord Faber, Silverberg, and Dong concluded that infection by inhalation occurred with greater ease than by ingestion.

7. Subcutaneous

Poliomyelitis virus can be found in the regional lymph nodes following injection by this route (Flexner and Lewis, 1910 *a*, *c*) Further, generalization may occur with the development of typical paralytic symptoms (Flexner and Lewis, 1909 *c*, 1910 *c*, Melnick and Paul, 1943)

8. Dermal

Earlier workers failed to transmit the infection by this route (see, e g., Rhoads, 1930). Trask and Paul (1936) found that a fresh strain (Wfd) was infective by this route (see also 1938, 1942 *b*) Other workers have also found that freshly isolated strains, e g, the Sacramento and Mar, may possess this property, but become noninfective on passage (Howitt, 1937 *a*, Burnet, Jackson, and Robertson, 1939 *b*, Burnet and Jackson, 1940, Stimpert and Kessel, 1940, Melnick and Paul, 1943) German and Trask (1938) found that the Wfd strain was still infective when inoculated in areas of skin apparently deprived of nerve supply After inoculation by this route, chimpanzees develop a subclinical infection and excrete virus in the stool (Melnick and Horstmann, 1947)

9. Intravenous

The intravenous route was used by a number of the earlier investigators (e g, Flexner and Lewis, 1909 *b*, 1910 *c*) It never gives very satisfactory results unless an

overwhelming dose is injected (Clark, Fraser, and Amoss, 1914). It has been estimated that to cause infection by intravenous injection, a dose 1,250 times more than that needed for intracerebral injection is necessary (Flexner and Amoss, 1914 *a*). After intravenous injection the virus is demonstrable in the blood for at least 72 hours At the time of onset of paralysis, however, it may have disappeared (Clark, Fraser, and Amoss, 1914); then it can be found in the spleen, marrow, and perhaps spinal ganglia (Flexner and Amoss, 1914 *b*). Animals are still susceptible if the olfactory route is blocked by section or application of zinc sulfate to the mucosa (Rasmussen and Clark, 1940).

Whether virus reaches the central nervous system or not, depends on the integrity of the *blood-brain barrier*. It was shown by Flexner and Amoss (1914 *b*, 1917 *b*) that intravenous injection resulted in paralysis more regularly if the meninges were irritated aseptically by intraspinal injections of serum, saline, or by causing some hemorrhage into the cerebrospinal fluid. Under such conditions, the intravenous infecting dose had only to be 50 times the intracerebral (instead of over 1,000) A similar result can be achieved by a previous intracerebral injection of starch, which serves to "fix" the virus in the central nervous system (Lennette and Hudson, 1936 *a*) Virus was demonstrated in the cerebrospinal fluid, when passage had been facilitated by serum injections, after 3 to 4 days, it persisted till the onset of paralysis (Flexner and Amoss, 1914 *a*).

The state of the blood-brain barrier in experimental poliomyelitis induced by various routes of infection has recently been investigated Thus, using intravenous injections of acid fuchsin and congo red, it was shown that the dye appears in the gray matter, due presumably to a somewhat increased vascular permeability in this area (Harmon and Krigsten, 1937) A slight increase in nitrate (Lennette and Reames, 1937, 1938), but a more definite increase in sodium bromide (Lennette and Campbell, 1937, 1938), has been noted in the CSF after intravenous injection

to the brain can be neutralized in the cerebrospinal fluid by intraspinal injections of immune serum (Flexner and Amoss, 1914 *b*) (Later papers which have con-

permeability are those of Kasahara,

Campbell, 1939, Lennette, Campbell,

The histological appearance of the central nervous system of monkeys injected intravenously differs somewhat from that following other routes of infection, thus the perivascular cuffing is more widespread and there is lymphocytic infiltration of the choroid plexuses (Flexner and Amoss, 1914 *b*).

10. Gastro-intestinal

Numerous workers have failed to infect monkeys orally (Landsteiner and Levaditi, 1909 *b*, Flexner and Lewis, 1910 *c*, Clark, Schindler, and Roberts, 1930, Lennette and Hudson, 1936 *b*, Rasmussen and Clark, 1940, Howe and Bodian, 1947 *b*).

Although rhesus monkeys are difficult to infect orally there is no doubt that some other monkeys (especially cynomolgi) and chimpanzees can be infected by certain strains administered by various methods

1. Simple swabbing of the pharynx with the unadapted Mar strain proved effective (Burnet, Jackson, and Robertson, 1939 *b*, Burnet, 1940)

2 Application to the tongue may rarely produce infection (Faber, Silverberg, and Dong, 1943 *a*) Insertion into the esophagus proved negative (Faber and Silverberg, 1942)

3 Animals may sometimes contract infection, and excrete virus in the stool, by drinking infected water, by eating infected cord, or foodstuffs such as bananas,

milk, and butter infected with virus (Kling, Levaditi, and Lépine, 1929, Levaditi, Kling, and Lépine, 1931; Saddington, 1931–2; Levaditi, Kling, and Hornus, 1933, Vignec, Paul, and Trask, 1939, Burnet, 1940; Trask and Paul, 1941 *b*, Howe and Bodian, 1941 *c*; Bodian and Howe, 1945 *b*). Melnick and Horstmann (1947) found that chimpanzees developed a subclinical infection and excreted virus in the stools

4. Leiner and Wiesner (1910 *a*) found that infection developed after ingestion, if the gut was paralyzed with opium

5. Horstmann *et al.* (1947) infected 2/7 baby rhesus monkeys by feeding with the rodent-adapted Ph and Y-SK strains Both animals developed paralysis, in the case of the animal infected with Ph, virus was recovered from the lymph nodes, wall of small intestine, heart muscle, spleen, and adrenals

Attempts have been made to see whether the upper or lower part of the alimentary system is the more susceptible. Using infected enemata, Faber, Silverberg, and Dong (1943 *a*) failed to produce infection In other experiments, they gave virus in fat-covered capsules that could be absorbed only from the gastro-intestinal mucosa; no infection resulted.

Other workers, however, have succeeded in infecting by stomach tube, rectal tube, or by inoculation into a loop of bowel (Kling, Levaditi, and Lépine, 1929, Levaditi, Kling, and Lépine, 1931, Clark, Roberts, and Preston, 1932, McClure, 1943). The lower part of the alimentary system is, therefore, susceptible, but there seems little doubt, from the experiments of Faber, Silverberg, and Dong (1943 *a*), and other observations, that the upper part of the alimentary tract, i e, the mouth, pharynx, and esophagus, is more vulnerable.

Investigations have beer [illegible] CNS after ingestion, administration by [illegible]
(1941 *c*, 1942 *a*, *b*) infectec [illegible]
thus excluding the olfactory pathway There was a good correlation between the development of bulbar paralysis and administration by the oral route. Virus probably reached the CNS by the 5th and perhaps the 9th nerve. After administration by stomach tube, the celiac and sympathetic ganglia were first involved, then the spinal cord After pharyngeal swabbing, the severest changes in the brain stem were found to be in the nuclei of the cranial nerves in the dorsal region of the medulla (Burnet, Jackson, and Robertson, 1931 *b*) After administration by stomach or rectal tube, McClure (1943) found lesions in the intervertebral ganglia, chiefly in the lower cervical and lumbosacral groups After ingestion, Burnet and Jackson (1940) recovered virus from the abdominal autonomic nerves, and abdominal lymph glands.

Evidently, therefore, virus entering through the upper part of the alimentary tract passes to the CNS via cranial nerves (see also section on inhalation above), virus absorbed through the intestines probably passes to the cord via sympathetic pathways.

Toomey's experiments Toomey and his associates have very strongly advocated the rôle of the gastro-intestinal tract in the pathogenesis of poliomyelitis (Toomey, 1931–2 *a*, 1932 *a*, *b*, *c*, Toomey and von Oettingen, 1932–3, Toomey, 1932–3, 1933–4 *b*, *d*, 1934 *a*, *c*, 1934–5 *a*, *b*, *c*, *d*, *1935 b*, *1936 b*, *c*, *d*, *e*, *f*, *1937 a*, *d*, *e*, Toomey and Weaver, 1936, 1937, Toomey and Tischer, 1943) The most important findings are as follows

1 A toxic factor which exerts a depressant and lethal effect on animals has been demonstrated in the urine and fec [illegible]
monkeys This "enteric tox [illegible]
intestinal organisms, such a [illegible]

2 Toomey carries out intestinal injection by clamping off a loop of gut and injecting virus "subserosally" Poliomyelitis follows injections of virus alone, but develops more quickly if the virus is combined with enteric toxin Subcutaneous injections of PCB filtrates or vaccines also render young monkeys more susceptible to subserosal injection of virus

3. Injections of PCB filtrate and virus into the motor area or the lumbar cord produce paralysis almost at once, whereas both components are harmless injected separately.

4 Following subserosal injections, the virus is thought to spread to the central nervous system by vagus and sympathetic nerve fibers The first histological changes in the central nervous system occur within 24 hours, and are noted in the spinal ganglia, and later in the anterior and posterior horns, where there is destruction of nerve cells Microglial proliferation takes place almost coincidentally with the nerve cell destruction Later (not before 5 days) well marked perivascular cuffing is present, but there is no meningitis The lumbar area is the most heavily affected, and usually before the other portions of the cord The fact that in the human disease also, the lumbar cord is frequently first involved has led to the suggestion that the route of infection in man is via the gastro-intestinal tract, but Faber (1935) has pointed out that *the lumbar cord is also first affected following nasal* instillation of virus

5. These experiments have been criticized in that the methods are too drastic and cannot simulate the natural route of infection in man (e g, Flexner, 1936). Toomey has countered with the evidence that, without such drastic measures, monkeys deficient in vitamin D are more readily susceptible to injection of virus than normal monkeys. Conversely, addition of vitamin D to the diet serves to protect animals from infection

11. Other Routes

Intraperitoneal. This route is usually combined with an intracerebral injection given at the same time (e.g, Landsteiner and Popper, 1908, Levaditi and Landsteiner, 1909, Flexner and Lewis, 1909 *a*, 1910 *c*, McIntosh and Turnbull, 1913)

The usual incubation period is not over 14 days, but it has been recorded that monkeys injected with virus may not develop symptoms of infection for as long as 6 to 10 months (Genevray and Dodero, 1934). McClure (1941 *b*) found changes in the sensory portions of the vagus ganglia, the intervertebral ganglia, and sometimes the gasserian ganglia

External ear. Monkeys can be infected after instillation of the external ear (Vieuchange, 1936 *a*) As no lesions of the auditory mucosa, tympanum or auditory nerve occur, it is presumed that the virus spreads to the central nervous system by the nerves innervating the external acoustic meatus

Tonsil Monkeys can be infected by dropping virus on to the tonsillar mucosa (Landsteiner, Levaditi, and Danulesco, 1911) Sabin (1938) infected monkeys by direct tonsillar injection, and found that they developed bulbar paralysis

Pulpal inoculation Aisenberg and Grubb (1943, 1945) inoculated the exposed pulps of the anterior teeth, and produced paralytic attack in 1 animal out of 5, the remainder developing nonparalytic symptoms

Injection after transection of the spinal cord Transection of the spinal cord has been carried out prior to injection of virus intracerebrally (Jungeblut and Spring, 1929–30, Toomey, 1933–4 *a*, *c*, Brodie and Elvidge, 1934) Injections have also been given into the cord below the section (Brodie and Elvidge, 1934). Intrasciatic nerve injections have also been used (Toomey, 1933–4 *a*, *c*)

It should be noted that in these experiments there was free circulation of the cerebrospinal fluid between the two cut portions of the cord. Therefore, if the cerebrospinal fluid was concerned in the spread of the virus, this should have been recoverable from the lower portion despite the section

Following intracerebral injection of such monkeys, it was found that typical poliomyelitis developed with the usual incubation period. Virus and histological lesions were present in the cord proximal to the section, but not distally. Virus [illegible]

of the virus by nerve tracts and not by the cerebrospinal fluid or other means Toomey's experiments, however, do not altogether confirm those of Jungeblut and Spring, or Brodie and Elvidge, for he was able to discover both virus and lesions

in the distal portion of the cord after intracerebral injection, and lesions proximally after intrasciatic injection He suggested that the virus had spread to the cord by the sympathetic nerves. Howe and Bodian (1941 *a*, 1942 *a*), like Toomey, found that virus could progress around a section of the cord. After intracerebral or nasal inoculation, virus and lesions were found in the distal portion. After sciatic nerve inoculation, virus might be found in the cord above the transection; they suggested that the paravertebral sympathetic chains were involved. A number of animals was subjected to bilateral sympathectomy of 2–3 ganglia at the level of the transection, virus was then inoculated into the lumbar cord. Virus progressed into the remainder of the CNS, they suggested that it spread from the lumbar cord to the wall of the gut via sympathetic fibers, and thence to the brain stem via the vagus.

At any rate, it would seem that all are agreed that the cerebrospinal fluid plays no part in the dissemination of the virus in this type of experiment.

Testicular injection gives a negative result (Jungeblut and Thompson, 1929–30)

Contact infection. Until recently there were no instances recorded of contact infection in monkeys, and there is every reason to believe that this is an extreme rarity. Howe and Bodian (1944 *b*) isolated virus from the stools of 2 uninoculated chimpanzees quartered for 6 months in cages adjoining those of a rhesus monkey inoculated nasally with a positive stool. "Spontaneous" poliomyelitis of monkeys has not been proved to occur. Any such apparent occurrence would raise the question of whether the monkeys had been used previously or whether they had become infected by contact.

THE FEATURES OF EXPERIMENTAL POLIOMYELITIS IN THE MONKEY

Speaking generally, the features of poliomyelitis are similar whatever the route of infection, any special differences or modifications have already been discussed under the heading of "routes of infection." These features have been described repeatedly, but comparatively little has been added to the early report of Flexner and Lewis (1910 *c*), and the following account is largely based on their paper, as well as personal observations

Incubation Period

The incubation period can vary from 4 to 33 days, but the great majority shows the first signs of nervous involvement after 7 to 10 days Certain monkeys will be found to be more resistant than others, but a batch of animals injected together usually shows the first manifestations more or less concurrently.

Incubation is partly dependent on dosage Small amounts cause infection after prolonged periods, and very large amounts may infect after a shorter period (Brodie, 1933 *b*, Moore *et al*, 1942, Moore and Kessel, 1943) The disease tends to be less severe if the incubation is prolonged.

Nonparalytic Attacks

After inoculation by any route, monkeys and chimpanzees may suffer from nonparalytic attacks, and recover before paralysis sets in (Brodie and Wortis, 1934, Kling *et al.*, 1942 *a*, *b*, Aisenberg and Grubb, 1945, Bodian and Howe, 1945 *a*). Such a diagnosis can be made only by histological examination, or isolation of virus from stool Sabin and Ward (1941 *c*) for example, found destruction of an appreciable number of anterior horn cells, with mesodermal-glial inflammation Bodian and Howe (1945 *b*) studied the condition in chimpanzees, and found that virus might be excreted in the stool for 3 days to 8 weeks after inoculation The changes in the brain and cord were similar to those in paralytic cases The severity of the pathological changes varied from a fully developed distribution of lesions in the brain and cord to mild scattered lesions in the brain only They found no support

for the occurrence of a purely systemic or peripheral form of poliomyelitis. The central nervous system was always involved.

Paralytic Attacks

In the prodromal period, the animal shows a rise in temperature and changes in the CSF (see below). It may be nervous, tremulous, and excited, with erect hairs. Spasticity of muscles may be noted, probably due to lesions in the brain only (*Bodian*, 1946).

The onset is usually sudden, the animal appearing to be more or less healthy, say in the evening, and the next morning showing an established paralysis. This paralysis is seen most commonly in both legs, and next most frequently in either one leg, one side of the face (Fairbrother and Hurst, 1930), or one arm. In certain rare cases where the cerebrum is severely involved, death eventuates in an apoplectic fit, before paralysis can appear.

Course

In severe infections, the paralysis extends rapidly to involve all the limbs. In more moderate cases it may progress rapidly, but only for about 24 hours, from which time slow improvement sets in. The animal is usually to be found sitting quietly in the cage, but on rousing, moves about as actively as the extent of paralysis allows. Teeth grinding and whining noises may be heard. In fatal cases, death occurs usually from 1 to 6 days after the onset of paralysis In convalescence, some degree of muscular wasting and atrophy develop in limbs which were severely paralyzed, in limbs less involved, however, there may be complete recovery, so that the animal is able to move and jump about as well as before. Such recovered animals prove immune on reinoculation A partly recovered monkey may suffer a fatal relapse (see Heaslip, 1938 *a*)

The transitory nature of the paralysis in some monkeys may be explained in two ways (Sabin and Ward, 1941 *c*) If only a few nerve cells are destroyed, normal function can be maintained with a reduced number of cells They found cells showing lesser degrees of damage in such animals, and suggested that probably not all nerve cells attacked by the virus are irreparably damaged

Taylor (1919) carried out an extensive series of blood counts in experimental poliomyelitis, and reported a polynucleosis in the preparalytic stage, with a lymphocyte crisis at the onset of symptoms The preparalytic polynucleosis was confirmed by Harmon, Shaughnessy, and Gordon (1931), but they did not agree that a lymphocyte crisis occurred

The carbohydrate mechanism is said to be deranged in experimental poliomyelitis (Jungeblut and Resnick, 1936). The blood sugar level does not actually show any alteration, but there is an increased tolerance for glucose, as evidenced by a slow response to the glucose tolerance test. This increased glucose tolerance does not depend on the state of involvement of the nervous system, but is evidently a systemic disturbance, possibly of endocrine origin

Normally, gold chloride solution causes a precipitation of brain and cord extracts The serum of monkeys suffering from poliomyelitis can prevent this action, whereas normal serum cannot The property is acquired as early as the disease as the second day, and disappears during convalescence. The stabilizing property of the serum resists 65° C for half an hour (Jungeblut, 1930–1 *a*).

An excellent index of the onset of nervous symptoms in the infected monkey is afforded by study of the temperature chart (Kramer, Hendrie, and Aycock, 1930, Jungeblut, 1931, Harmon, Shaughnessy, and Gordon, 1931, Brodie and Wortis, 1934) The temperature rises, even to 105° F. (normal monkey temperature up to 103° F) during approximately the 3 days before the first clinically recognizable manifestations of infection, with the progress of the disease the temperature drops to subnormal The terminal hypothermia is not associated with a lowered vitamin

in the distal portion of the cord after intracerebral injection, and lesions proximally after intrasciatic injection He suggested that the virus had spread to the cord by the sympathetic nerves. Howe and Bodian (1941 *a*, 1942 *a*), like Toomey, found that virus could progress around a section of the cord After intracerebral or nasal inoculation, virus and lesions were found in the distal portion. After sciatic nerve inoculation, virus might be found in the cord above the transection; they suggested *that the paravertebral sympathetic chains were involved*. A number of animals was subjected to bilateral sympathectomy of 2–3 ganglia at the level of the transection, virus was then inoculated into the lumbar cord. Virus progressed into the remainder of the CNS, they suggested that it spread from the lumbar cord to the wall of the gut via sympathetic fibers, and thence to the brain stem via the vagus.

At any rate, it would seem that all are agreed that the cerebrospinal fluid plays *no part in the dissemination of the virus in this type of experiment*

Testicular injection gives a negative result (Jungeblut and Thompson, 1929–30)

Contact infection. Until recently there were no instances recorded of contact infection in monkeys, and there is every reason to believe that this is an extreme rarity. Howe and Bodian (1944 *b*) isolated virus from the stools of 2 uninoculated chimpanzees quartered for 6 months in cages adjoining those of a rhesus monkey *inoculated nasally with a positive stool*. "Spontaneous" poliomyelitis of monkeys has not been proved to occur. Any such apparent occurrence would raise the question of whether the monkeys had been used previously or whether they had become infected by contact.

THE FEATURES OF EXPERIMENTAL POLIOMYELITIS IN THE MONKEY

Speaking generally, the features of poliomyelitis are similar whatever the route of infection, any special differences or modifications have already been discussed under the heading of "routes of infection." These features have been described repeatedly, but comparatively little has been added to the early report of Flexner and Lewis (1910 *c*), and the following account is largely based on their paper, as well as personal observations.

Incubation Period

The incubation period can vary *from 4 to 33 days, but the great majority* shows the first signs of nervous involvement after 7 to 10 days Certain monkeys will be found to be more resistant than others, but a batch of animals injected *together usually shows the first manifestations more or less concurrently*

Incubation is partly dependent on dosage Small amounts cause infection after prolonged periods, and very large amounts may infect after a shorter period (Brodie, 1933 *b*, Moore *et al*, 1942, Moore and Kessel, 1943) The disease tends to be less severe if the incubation is prolonged.

Nonparalytic Attacks

After inoculation by any route, monkeys and chimpanzees may suffer from [illegible] before paralysis sets in (Brodie and Wortis, 1934, [illegible] and Grubb, 1945, Bodian and Howe, 1945 *a*). [illegible] by histological examination, or isolation of virus [illegible] 1 *c*) for example, found destruction of an appreciable number of anterior horn cells, with mesodermal-glial inflammation Bodian and Howe (1945 *b*) studied the condition in chimpanzees, and found that virus might be excreted in the stool for 3 days to 8 weeks after inoculation The changes in the brain and cord were similar to those in paralytic cases. The severity of the pathological changes varied from a fully developed distribution of lesions in the brain and cord to mild scattered lesions in the brain only. They found no support

In experiments conducted over a period of about a year, fluids obtained in the early stages showed a predominance of polymorphs, with lymphocytes in excess at the onset of paralysis. Then for some reason later in the year's work there came a period when the cell pictures were chiefly monocytic.

REFRACTORY STATE OF REGENERATING NERVE CELLS

Howe and Bodian (1939 *b*, 1942 *a*) demonstrated this phenomenon in a series of monkeys infected by intranasal inoculation. In one group, the sciatic nerve was sectioned 3–4 days before the development of paralysis in the legs. The anterior horn cells of the sectioned and control sides were both completely destroyed, the destruction of the cells on the sectioned side appeared to begin earliest. In another group, the sciatic nerve section was carried out earlier, between 6 and 57 days before the onset of leg paralysis. In this group, the anterior horn cells on the control side were all destroyed by the action of the virus. On the sectioned side, the vast majority of cells giving rise to the sciatic nerve was spared by the virus.

A similar refractory state of neurons has been demonstrated in the olfactory bulbs (1941 *b*, 1942 *a*). They sectioned the olfactory tracts, and found that after a few days no changes occurred in the bulbs on nasal inoculation. This refractory state was associated with shrinkage and chromatolysis of the mitral cells, and lasted for a considerable period.

In their work on sciatic inoculation fully described on page 974, Howe and Bodian showed that axons will not conduct virus when they are regenerating following section. Evidently, therefore, both neurons and axons undergoing metabolic disturbance associated with regeneration are refractory to attack by virus.

DISTRIBUTION OF VIRUS IN EXPERIMENTAL POLIOMYELITIS

A number of observations has already been mentioned, when discussing the routes of inoculation.

Central nervous system. Brodie (1932 *a*, 1933 *a*) has estimated the virus content of various parts of the central nervous system at the height of the disease. The spinal cord, brain stem, midbrain, and diencephalon contain 92 per cent. of the total virus content, while the basal ganglia, cerebral cortex, and cerebellum, though weighing 3 times as much, only contain 8 per cent.

Virus has not usually been detected in the cord before the onset of paralysis, but is constantly present in large quantity at its height. Thereafter, it rapidly decreases in amount, so that about 3 weeks after the appearance of paralysis the cord may prove noninfective (see, e.g., Fairbrother, 1930, Brodie, 1932–3). The "growth curve" of virus (Lansing strain) in the cord following intracerebral injection has been investigated by Bodian and Cumberland (1947). A period of exponential multiplication occurs over less than 2 days, the average peak being before the onset of paralysis, the average period of maximal concentration is sustained only through the day preceding paralysis and the first day of paralysis. A sharp decline in multiplication takes place on the second day of paralysis, but virus persists in small quantities for at least 2 weeks.

A rare case has been recorded by Brodie (1934–5 *b*) where a monkey showed the presence of virus in the cord without any accompanying histological lesions.

Cerebrospinal fluid. After direct intrathecal injection, the virus is demonstrable for at least 5 days, but is usually absent at the onset of paralysis (Clark and Amoss, 1914, Hurst, 1931).

After other routes of injection, virus may be found, but this is a rare occurrence (Flexner and Lewis, 1910 *c*, *d*, Fairbrother and Hurst, 1930, Hurst 1930, 1932). However, Schaeffer and Muckenfuss (1938) have claimed that virus enters the cerebrospinal fluid rapidly after intracerebral injection.

B_2 reserve (Kolochine-Erber and Raffy, 1944, 1946). In certain cases, the dromedary type of chart may be found, with two well marked rises of temperature in the incubation period (Harmon, Shaughnessy, and Gordon, 1931).

According to Brodie and Wortis (1934), poliomyelitis infection of monkeys may present in 1 of 4 forms (1) nonparalytic (see above), (2) the ordinary spinal form, with or without a prodromal period; (3) a short progressive type like Landry's paralysis, (4) a diphasic type.

Physiological Reactions of Peripheral Nerves

The physiological state of the peripheral nerves after intracerebral injection of virus has been investigated (1, Covell and O'Leary, 1932; 2, Bishop, Heinbecker, and O'Leary, 1932, 3, Heinbecker, Bishop, and O'Leary, 1932; 4, O'Leary, Heinbecker, and Bishop, 1932; 5, Covell, 1932)

The investigation was carried out by using neutral red to demonstrate degenerating myelin, by testing the nerve conduction rates, and by applying galvanic stimulation to the spinal cord and examining for muscle contraction in the area supplied The following is a résumé of the main conclusion of these investigators

(*a*) During the late preparalytic and early paralytic stage there is a definitely increased irritability of the peripheral nerves as indicated by an increased conduction rate and shorter refractory period It should be mentioned that some days before the end of the incubation period there are definite modifications in chronaxia, but that these occur equally in paralytic and nonparalytic cases (Chauchard *et al*, 1934). The nerve fiber shows definite cellular alterations, probably due to an intrinsic action of the virus

(*b*) For a considerable part (4 to 10 days) of the paralytic stage, many nerve fibers can themselves conduct nerve impulses Stimulation of the cord from the first days of paralysis onward fails to elicit a response, however, the anterior horn cells being unable to conduct impulses

(*c*) The nerve cells, though damaged as regards impulse transmission, continue to exert a trophic influence over the nerve fibers

(*d*) In the last stages of paralysis, even stimulation of the nerves fails to elicit a response.

(*e*) Stimulation applied direct to the muscles always elicits contraction

The Cerebrospinal Fluid

Following nasal instillation of virus, changes are always found in the cerebrospinal fluid, even if no symptoms of infection are manifest (Gay and Lucas, 1910, Flexner, 1933 *a*, *b*, 1935 *a*) Even 48 hours after nasal instillation, there develops a definite pleocytosis, the cells being mainly lymphocytes, although in the early stages polymorphs may constitute 60 per cent. of the total count Less constantly, there is an increase in globulin The rise in cell count, which often corresponds with a pyrexial period, may reach 70 cells per c mm. after 48 hours, and 300 cells per c.mm after 4 days In the prodromal period a usual figure is 1,000 cells per c.mm., mainly lymphocytes.

As is well known, monkeys frequently resist one nasal instillation though succumbing on repetition Examination of the cerebrospinal fluid after each such inoculation shows, however, that the characteristic reaction just described has occurred. At the onset of paralysis the majority of cerebrospinal fluids shows a colloidal gold curve with a well-marked luetic reaction, with the progress of the infection this returns to normal (Jungeblut and Khorazo, 1930)

Following intracerebral injection also, changes are to be found in the cerebrospinal fluid, and are of the same nature as those just described, pleocytosis and globulin being found, often at least 48 hours before the onset of paralysis (see Mollaret and Erber, 1934) No change was detected in the vitamin C content of

poliomyelitis (Kasahara and Gammo, 1938)

ed the cytology of fluid removed from the

maximum at the stage of complete paralysis

which lasted for another few days. In such cases the olfactory bulbs showed histological lesions as already described On the other hand, if the bulbs were removed no fever developed

The second method of preventing poliomyelitis following nasal instillation consists in treating the relatively exposed olfactory nerve endings with chemical substances It was shown by Armstrong and Harrison (1935) that the nasal instillation of 4 per cent. sodium alum sulfate secured the survival of almost three-quarters of a batch of monkeys subsequently inoculated intranasally with virus (see also *Haber and Coquoin-Carnot, 1937*)

Later, Armstrong and Harrison (1936 *a*) showed that 3 to 6 instillations of picric acid, with or without alum, were more effective than alum only Also, it was found that the effects were cumulative, 6 instillations giving more protection than 3 Picric acid was also found to be effective (Schultz and Gebhardt, 1936) After such a course, the nasal mucosa is resistant to infection for from 1 to 2 months (Sabin, Olitsky, and Cox, 1936) Armstrong and Harrison also showed that unless the instillation was adjusted to a pH sufficiently acid to cause coagulation of protein, no protection resulted (1936 *b*)

Other substances found to be effective were picric acid plus sodium aluminum sulfate (Armstrong and Harrison, 1936 *b*, Sabin, Olitsky, and Cox, 1936), 3 per cent tannic acid (Sabin, Olitsky, and Cox, 1936, see also Olitsky and Cox, 1934), 1 per cent. nitrophenol, 1 per cent trinitrocresol, and 1 per cent mercurochrome (Schultz and Gebhardt, 1936), pituitrin S and adrephine (Kramer, Grossman, and Parker, 1937, 1938) Later reports suggest that zinc sulfate is the best of all substances so far tested (Schultz and Gebhardt, 1936-7, Olitsky and Sabin, 1937) As described elsewhere, these results have been applied to man, but with negative results

It has been said that not only does nasal instillation of such chemicals protect against infection by the nasal route but also by the intravenous route, thus, Armstrong (1936 *a*) found that poliomyelitis did not develop in monkeys with chemically treated nasal mucosae on injection intravenously This confirms the parallel observation of Lennette and Hudson (1934-5) who injected monkeys intravenously after section of the olfactory tracts, and found that no infection developed However, certain apparently contradictory reports have appeared Thus, German and Trask (1938) reported that bilateral olfactory neurectomy did not inhibit the development of infection following intravenous or intracutaneous inoculation (see also Toomey, 1939 *a*) Further, intranasal zinc sulfate has been said not to prevent the development of infection after intravenous inoculation (Toomey and Takacs, 1938 *a*)

The effect of intranasal instillation of 1½ per cent zinc sulfate is to cause necrosis of the mucous membrane of the olfactory area By the end of 3 to 4 days, however, the epithelium is again normal (Schultz and Gebhardt, 1938)

A large number of chemicals was tested by Schultz and Gebhardt (1942) who found that they differed considerably in their ability to induce resistance Zinc sulfate was the most effective because it caused the severest damage There was an extensive coagulative necrosis of the olfactory epithelium which separated *en masse* from the lamina propria New epithelium grew in later The resistant state might not be established for 2 or 3 days after application Probably animals can always be infected 3 to 6 months later

Chemotherapy

Various drugs have been said to exert some action either in preventing or modifying the attack (Jungeblut, 1930-1 *b*, Hornus and Haber, 1934) antimony, potassium tartrate, neostibosan, mercurochrome, chaulmoogra oil, hexylresorcinol, and solganal Injections of vitamin C have been said to modify the infection (see p 1011)

A number of drugs has been found devoid of effect hexamethylamine, sodium ricinoleate, acriflavine, and tryparsamide (Jungeblut, 1930-1 *a*, Kolmer and Rule, 1933-4 *b*) Luminal, insulin, and metrazol shock did not influence the infection (Jungeblut, 1940) Continuous intravenous hypotonic saline produced no apparent benefit (Kramer, Geer, and Himes, 1942) Potassium chlorate does not appear to have much effect (Arthus *et al*, 1939, Saucier and Stewart, 1940, Levinson and Milzer, 1941).

Nervous ganglia. The virus can be found in the intervertebral, gasserian and abdominal sympathetic ganglia; histologically, there are to be found interstitial changes of perivascular cuffing, and cellular infiltrations with some neuronophagia (Flexner, Clark, and Amoss, *1914 b*; *Hurst, 1929*).

Peripheral nerves. The virus can be found in the sciatic nerve at the height of infection following intracerebral injection (Nicolau, Dimancesco-Nicolau, and Galloway, 1929).

Blood. The virus is very seldom to be found in the blood of infected monkeys (Flexner and Lewis, *1910 c*; *Flexner and Clark, 1911*; *Clark, Fraser, and Amoss,* 1914; Gordon and Lennette, 1939). Melnick (1944 *b*) examined one recently isolated strain that showed a special tendency to invade the blood.

Salivary glands. The virus has rarely been found in this site (Landsteiner and Levaditi, *1909 b*).

Nose and throat. The virus can be demonstrated in the following sites nasal mucosa (Flexner and Lewis, 1910 *c*; Landsteiner, Levaditi, and Danulesco, 1911), tonsil and peritonsillar region (Flexner and Lewis, 1910 *c*, Flexner and Clark, 1911, Landsteiner, Levaditi, and Danulesco, *1911*); *nasopharyngeal mucosa* (Flexner and Lewis, 1910 *b*, *c*, Flexner and Clark, 1911, Landsteiner, Levaditi, and Danulesco, 1911), even after 5½ months (Osgood and Lucas, 1911).

Lymph nodes Virus may be found in the regional lymph nodes following subcutaneous injection (Flexner and Lewis, *1910 a, c*). After intracerebral and intraperitoneal injection, Kling, Olin, and Gard (1938) isolated virus from inguinal and mesenteric glands.

Spleen. Virus has been demonstrated in the spleen (Lennette, 1937).

Intestinal tract. Virus can be recovered from the intestines or stools of monkeys, and particularly of chimpanzees, infected by the usual routes (Kramer, Hoskwith, and Grossman, 1939; Melnick, 1943 *a*, 1944 *b*, Howe and Bodian, 1944 a, Melnick and Horstmann, 1947) Melnick (1946 *b*) examined stools by his ultracentrifugation technique, and found that they might be positive in the incubation period. Virus appeared more readily when the inoculation was given peripherally, subcutaneous and intracutaneous inoculation gave positive stools more commonly than intracerebral inoculation. Several strains acted in this fashion. Trask and Paul (1941 *b*) also found virus in the stool after intracutaneous inoculation A number of workers has recovered virus after infecting animals by the gastro-intestinal tract (see above)

TREATMENT OF EXPERIMENTAL POLIOMYELITIS

Treatment of the Olfactory Nerves

Schultz and Gebhardt (1933–4*b*) were the first to show that nasal instillation does not produce poliomyelitis if the olfactory bulbs and tracts are previously destroyed *This important observation has been confirmed by* Lennette and Hudson (1934–5), Brodie and Elvidge (1934), and Howe and Ecke (1937–8 *b*) In these experiments, the olfactory bulbs and tracts were usually cauterized, and some days or months later, the animals were inoculated intranasally. Control untreated *monkeys* developed poliomyelitis, but those that were treated survived The treated monkeys were not, however, resistant to a subsequent injection given intracerebrally

Lennette and Hudson (1934–5) made the additional observation that poliomyelitis did not develop after intravenous injection in monkeys with severed olfactory tracts, this suggests that any virus entering the blood stream is excreted into the nasal passages, and thence ascends to the brain by the olfactory nerves. As the 5th and 7th nerves are not damaged by these operative procedures, it is evident [illegible] does not travel along them, otherwise poliomyelitis would still develop [illegible] oted that if the olfactory tracts only were severed, [illegible] was actually an attack of *fever after 3 to 7 days*

of the nose or nasopharynx into the cervical sympathetic ganglia, and thence to the upper thoracic cord (see p. 978).

Monkeys can also be infected by pharyngeal swabbing, ingestion, or stomach tube After swabbing or ingestion, virus probably reaches the brain stem by the 5th and perhaps the 9th and 10th nerves. When virus is absorbed from the intestines it is probable that it spreads by the sympathetic fibers to the sympathetic ganglia and cord, or by the vagus to the brain stem (see p 979).

Howe and Bodian (1942 *a*), as a result of their extensive experiments, suggested that virus can reach the CNS by passage along both motor and sensory fibers They did not find the sympathetic fibers to be especially susceptible, although they were sometimes concerned, e g., in spread from the intestine, and spread after transsection of the cord

Following subcutaneous inoculation, virus can be detected in regional lymph nodes, and thereafter generalizes, presumably by the blood (see p. 978).

Dermal inoculation may also prove infective, even apparently in the absence of intact nerve fibers in the area (see p. 978), presumably virus must leave the area by lymph or blood

Blood may become infected with virus not only by direct intravenous injection, but also through infected lymph. It is extremely difficult to infect by the intravenous route unless the blood brain barrier is artificially rendered more permeable (see p. 978) It is possible that virus in the blood may not invade the CNS through the blood brain barrier but by excretion into the nasal passages, and thence via the olfactory nerves

We may conclude that after certain methods of inoculation, virus may spread by blood or lymph to the CNS Even in such cases, however, neural pathways may also be involved

The rôle of the cerebrospinal fluid It has been suggested that virus, having reached the cerebrospinal fluid, either by perineural lymphatics or by the blood, is disseminated by the fluid throughout the central nervous system Little attention need be paid to this theory, because a *sine qua non* of its acceptance would be the frequent demonstration of virus in the cerebrospinal fluid but it is found only after direct intrathecal injection, or after intravenous injection if aseptic meningitis is produced by intraspinal injection of serum (Flexner and Amoss, 1914 *a*). The upholders of this theory postulate that the virus passes into the parenchyma of the cord along the perivascular spaces (see, e g, Harbitz and Scheel, 1907 *a*, *b*, Clark and Amoss, 1914). Only under exceptional circumstances, however, such as do not occur in poliomyelitis, is this the direction of flow in these spaces, normally the flow is from within outward, and not vice versa In confirmation, Kempf and Soule (1939) were unable to recover from the CNS any significant amount of antisheep

tions of Hurst and others (*vide infra*) show, however, that nerve cell destruction is the primary change, and not meningitis Furthermore, any areas of meningitis present do not necessarily overlie the areas of greatest parenchymatous change, as should occur if the virus spreads directly inward It may fairly be assumed, therefore, that the cerebrospinal fluid plays little part in the primary dissemination

The Spread of Virus in the Central Nervous System

The classical work on the spread of virus following intracerebral, intrathecal, and intrasciatic injection using histological methods is that of Hurst and of Fair-

Sulfonamides have proved quite ineffective in preventing the onset or modifying the course of infection (Kelson, 1937; McKinley, Acree, and Meck, 1938, Toomey and Takacs, 1938 *b*, 1939, Rhodes and van Rooyen, 1938; van Rooyen and Morgan, 1943).

Blood obtained from an infected *M. mulatta* and treated with UVL did not modify the severity of the disease (Toomey and Takacs, 1943).

Here it may be mentioned that Jungeblut and Kopeloff (1931) found that a preexistent infection with *T. equiperdum* resulted in a prolonged incubation

Physical Treatment

X-rays produced harmful effects (Amoss, Taylor, and Witherbee, 1919, Lenz and Jungeblut, 1931–2).

Pyrotherapy applied in the incubation period was not capable of preventing the subsequent development of poliomyelitis, according to Jungeblut and Kopeloff (1931). However, Wolf (1934–5) reported that he was able to prevent the disease by treating during the incubation period.

PATHOGENESIS OF EXPERIMENTAL POLIOMYELITIS

In this section will be discussed the method whereby the virus spreads from the site of entry to the central nervous system, many facts in this connection have already been mentioned in this chapter.

A number of reviews on this subject, with reference to the human disease also, has appeared in recent years (e g, Report of the International Committee, 1932, Faber, 1933, Lovett, 1934, Doerr and Seidenberg, 1936–7; Kauders, 1937 *a*), Faber's (1933) paper puts forward convincingly the theory of spread by axonal routes

Portal of Entry to the Body

Monkeys can be infected most readily by intracerebral or intranasal inoculation, by exposure to atomized virus, or by application of virus to the sciatic nerve, other routes of infection are the intra-ocular, subcutaneous, dermal, intravenous, intraperitoneal, intratonsillar, and gastrointestinal

Passage of the Virus to the Nervous System

When virus is introduced other than by direct inoculation in the brain or cord, there are various paths open for spread to the CNS The simplest method of tracing the spread of virus is by histological examination, especially of the various ganglia, where the involved neurons occur and show degenerative changes. It appears that care must be taken, however, in drawing conclusions from the mere presence of lesions in ganglia Bodian and Howe (1947) reported that "control" chimpanzees may show accumulations of inflammatory cells similar to those found in inoculated animals.

By nerve paths Numerous observations have shown that following inoculation by peripheral routes, virus travels to the central nervous system by nerve paths For example, following inoculation of the sciatic nerve, virus spreads centrally, and the rate has been measured Virus can only spread in fibers that are both anatomically and physiologically normal Regenerating fibers will not conduct. Virus spreads actually in the axon, and not in the sheath

Following intra-ocular injection, virus probably travels via the optic nerve or by the ciliary ganglia and oculomotor nerves (see p 976)

Following intranasal inoculation, virus spreads by the olfactory nerves to the bulbs, and thence by the tracts to the brain This spread can be prevented by the application of chemicals that destroy the nerve endings, or by section of the fibers (see p. 986).

When animals are exposed by inhalation of atomized sprays, virus passes to the CNS either by the olfactory nerves, or by the afferent fibers of the trigeminal to the gasserian ganglion. Less commonly the pathway consists of the sympathetic fibers

of the nose or nasopharynx into the cervical sympathetic ganglia, and thence to the upper thoracic cord (see p 978).

Monkeys can also be infected by pharyngeal swabbing, ingestion, or stomach tube. After swabbing or ingestion, virus probably reaches the brain stem by the 5th and perhaps the 9th and 10th nerves When virus is absorbed from the intestines it is probable that it spreads by the sympathetic fibers to the sympathetic ganglia and cord, or by the vagus to the brain stem (see p. 979)

Howe and Bodian (1942 *a*), as a result of their extensive experiments, suggested that virus can reach the CNS by passage along both motor and sensory fibers. They did not find the sympathetic fibers to be especially susceptible, although they were sometimes concerned, e g, in spread from the intestine, and spread after transsection of the cord

Following subcutaneous inoculation, virus can be detected in regional lymph nodes, and thereafter generalizes, presumably by the blood (see p 978).

Dermal inoculation may also prove infective, even apparently in the absence of intact nerve fibers in the area (see p. 978), presumably virus must leave the area by lymph or blood.

Blood may become infected with virus not only by direct intravenous injection, but also through infected lymph It is extremely difficult to infect by the intravenous route unless the blood brain barrier is artificially rendered more permeable (see p. 978). It is possible that virus in the blood may not invade the CNS through the blood brain barrier but by excretion into the nasal passages, and thence via the olfactory nerves.

We may conclude that after certain methods of inoculation, virus may spread by blood or lymph to the CNS Even in such cases, however, neural pathways may also be involved

The rôle of the cerebrospinal fluid It has been suggested that virus, having reached the cerebrospinal fluid, either by perineural lymphatics or by the blood, is disseminated by the fluid throughout the central nervous system Little attention need be paid to this theory, because a *sine qua non* of its acceptance would be the frequent demonstration of virus in the cerebrospinal fluid but it is found only after direct intrathecal injection, or after intravenous injection if aseptic meningitis is produced by intraspinal injection of serum (Flexner and Amoss, 1914 *a*). The upholders of this theory postulate that the virus passes into the parenchyma of the cord along the perivascular spaces (see, e g, Harbitz and Scheel, 1907 *a*, *b*, Clark and Amoss, 1914). Only under exceptional circumstances, however, such as do not occur in poliomyelitis, is this the direction of flow in these spaces, normally the flow is from within outward, and not vice versa In confirmation, Kempf and Soule (1939) were unable to recover from the CNS any significant amount of antisheep hemolysin administered along with virus cisternally

As a preliminary to the actual entrance of the virus to the cord a stage of meningitis is postulated (e g, by Flexner and Amoss, 1914 *b*) The experimental observations of Hurst and others (*vide infra*) show, however, that nerve cell destruction is the primary change, and not meningitis Furthermore, any areas of meningitis present do not necessarily overlie the areas of greatest parenchymatous change, as should occur if the virus spreads directly inward It may fairly be assumed, therefore, that the cerebrospinal fluid plays little part in the primary dissemination of the virus following injection by routes other than intrathecal In all probability, however, once the virus has actually reached the parenchyma of the central nervous system, it may be spread secondarily by the cerebrospinal fluid, accounting for the patchy meningitis usually present (Fairbrother and Hurst, 1930)

The Spread of Virus in the Central Nervous System

The classical work on the spread of virus following intracerebral, intrathecal, and intrasciatic injection using histological methods is that of Hurst and of Fair-

brother. These papers have already been mentioned in the appropriate sections (Hurst, 1929, 1930, 1932; Fairbrother and Hurst, 1930). Numerous other workers have also studied the problem by histological methods (Faber and Gebhardt, 1932–3; Pette, Demme, and Kornyey, 1932, Hudson, Lennette, and Gordon, 1936, Howe and Ecke, 1937–8 *a*, Luhan, 1937, Bodian and Howe, 1939; Howe and Bodian, 1942 *a*).

Brodie (1932 *a*, 1933 *a*) investigated the question by means of titrations of various parts of the nervous system, and his observations confirmed those of the histological workers.

The general opinion of these workers is that virus spreads from the olfactory tracts or site of cerebral inoculation to many parts of the brain, by definite, often decussating, nerve paths In the cerebral cortex, however, the nerve cells are relatively resistant to the virus and little intrinsic change takes place therein, although the interstitial tissues react. Correspondingly, only a small quantity of virus can be demonstrated in the cerebral cortex Virus also spreads via the basal nuclei and medulla to the cord, where it can be demonstrated in large quantities. The results of transection experiments (see p. 981) have helped to confirm the validity of the theory of axonal spread. If virus is injected intracerebrally in a monkey in which the spinal cord has been severed, then only the proximal portion contains virus or shows lesions.

Howe and Bodian (1942 *a*) have shown that in the preparalytic stage, after the onset of fever, there may be a localization of histological changes along certain paths, depending on the portal of entry. By the time paralysis develops, virus has reached the preferential paths from the portal of entry, e.g, the nose or cortex, to the cord, and has passed rostrally and caudally along these paths There then follows a spread of virus to less susceptible centers. This secondary spread may occur even in the early stages when virus is inoculated in the frontal lobe. The final picture is similar with any portal of entry. Howe and Bodian (1942 *a*) point out that the final distribution of the histological changes is determined by at least 3 factors the differential susceptibility of certain centers, accessibility of the center to virus as determined by neuronal connections, the portal of entry

THE PRIMARY TISSUE REACTION IN EXPERIMENTAL POLIOMYELITIS

Poliomyelitis virus causes degenerative changes in the neurons and a mesodermal-glial inflammatory reaction. The work of Hurst (1929) and Fairbrother and Hurst (1930) conclusively showed that the primary attack of the virus is on the neuron

of Bodian and Howe (1941 *a*) and Howe and Bodian (1942 *a*). These authors performed hemidecortication in rhesus monkeys, which caused large areas of the thalamus to become devoid of nerve cells, neuroglia, vessels, and perivascular tissue were left intact Normally the thalamus is susceptible to virus, but when inoculation was carried out onto this neuron-denuded area, the mesodermal-glial inflammatory reaction did not develop. Both focal and perivascular lesions occurred in nearby areas where the nerve cells had not undergone retrograde degeneration.

For some reason, which is obscure, poliomyelitis virus shows a special tendency to attack anterior horn cells, and to a lesser extent neurons in the cerebrum and midbrain. Certain areas are normally highly resistant and show no lesions Even if virus is inoculated directly into such areas, e g, the lateral geniculate body or occipital lobe, mesodermal-glial lesions develop only in the immediate vicinity of the inoculum (Bodian and Howe, 1941 *a*, Howe and Bodian, 1942 *a*)

It seems probable that the attack of virus may be on the cytoplasm rather than the nucleus Bodian (1945) examined a rhesus monkey killed in the acute stage,

neurons in the brain, cord, and spinal ganglia.
ntaining 2-6 nuclei, showed degenerative
always showed identical changes, suggesting
toplasm, and that the nuclear changes are
secondary.

It is quite definitely established that neuronal damage is primary, and not secondary, to nearby perivascular infiltration or overlying meningitis. Howe and Bodian, with other workers, conclude that the mesodermal-glial response is sec-... to the interaction of virus with susceptible neurons, and is not due to a ... tissues

virus is not only neurotropic
(Hurst), but is neuronotropic,
its growth upon, living nerve
cells of certain types.

THE PATHOLOGICAL FEATURES OF EXPERIMENTAL POLIOMYELITIS

The Nonparalytic Stage

From experiments on chimpanzees and rhesus monkeys it has been concluded that the disease can be spontaneously arrested at any stage after entry of the virus into the CNS, before or even after the onset of paralysis (Bodian and Howe, 1941 *d*, Howe and Bodian, 1942 *a*)

The minimal degree of change observed in nonparalytic cases is a regional destruction of neurons and mesodermal-glial infiltration, at and near the site of entry of virus into the CNS. The cord may not be involved, and the full distribution of cerebral changes may not occur.

After intranasal inoculation, there may be a severe encephalitis rostral to the medulla, but no involvement of the cord

The maximal degree of pathological change observed in nonparalytic cases is practically equivalent in distribution and severity to the pathological involvement in paralytic cases The absence of detectable paralysis is due to the fact that the distribution of the destroyed neurons is too scattered to involve a single functional muscle group sufficient to produce clinically evident paralysis.

The Paralytic Stage

These features have, of course, been recorded by many authors (e g, Flexner ... 1911 *a*, Hurst, 1929, 1931, Pette,
following description, referring mainly to the ... intracerebral injection,[1] is largely that given by Hurst in his paper (1929), now regarded as one of the most important contributions to the histological study of poliomyelitis

The cord Irrespective of the portal of entry, the cord shows the greatest intensity of inflammatory change of any part of the CNS The changes predominantly involve the lumbar and cervical enlargements, although no portion is entirely free The lumbar cord is said to be particularly involved after intestinal and intrasciatic injection

... variable feature, but is usually
...phocytes predominate in the in-
... numbers of polymorphs may

[1] For a fuller description of the changes in the early stages of poliomyelitis following intracerebral injection, see the section on "routes of infection" In this section also, the pathological features of poliomyelitis following other routes of injection are more fully described

be present. The areas of meningitis are not necessarily related to underlying lesions in the gray matter. After intrasciatic injection, lumbar meningitis is usually intense

Perivascular infiltration is also a variable feature; the infiltrating cells are mainly lymphocytes, but in the early stages polymorphs may also be present (see Fig. 43). It is important to note that perivascular infiltration may be quite absent in the presence of severe nerve cell destruction, and therefore is not the primary change

Diffuse and focal cellular infiltrates are frequently present, especially in the anterior and posterior horns, and gray commissure, the cells are usually lymphocytes, although in the severer cases polymorphs may be found

Definite proliferation of the microglia occurs, and using Del Rio Hortega's silver stain, Hurst was able to show the true nature of these cells; they had puzzled many earlier workers who called them "polyblasts" or "elongated glial cells" The

FIG 43 Photomicrograph of an histological section through the spinal cord of a rhesus monkey infected with poliomyelitis virus, showing degeneration of nerve cells together with lymphocytic infiltration around two blood vessels Stained hematoxylin and eosin × 250

microglia may undergo degenerative changes consisting of thickening and eventual disappearance of the processes, and coarsening and vacuolation of the protoplasm

The most important change of all, however, is that in the nerve cells In the anterior horns of the cervical and lumbar regions, up to 50 per cent. of the available cells may be destroyed (see Fig 43) Cells in the posterior horns (especially Clarke's column) may undergo similar changes In the preparalytic stage the nerve cells show at most only early degenerative changes, but within 24 hours they have become totally destroyed Increasingly severe lesions can usually be observed with the progress of the infection, e g, central chromatolysis, complete dissolution of the Nissl substance, swelling and vacuolation of the cytoplasm, the nucleus disappears or alternatively becomes hyperchromic and excentric, neuronophagia ensues and polymorphs and microglia remove the effete cell In certain very acute cases the nerve cells appear to be killed more or less instantaneously and show little in the way of change. The nucleolus may be enlarged or mulberry-shaped (Hurst,

1931). Parallel changes to those detected by ordinary staining methods have been studied by the micro-incineration technique.

If the animal recovers after a severe attack of paralysis, there is a noticeable diminution in the numbers of anterior horn cells, with reactionary increase in the microglia and neuroglia

Burnet, Jackson, and Robertson (1939 *b*) found the changes in cynomolgus monkeys to be more diffuse than those in rhesus animals. The inflammatory reaction was intense in the cynomolgus monkey, and characterized by the presence of

CSF were associated
nfiltration.
ges (pial and perivascular infiltrations) are related to the 4th ventricle. There is some nerve cell destruction, but neuronophagia is rare Lesions around the 4th ventricle are most pronounced after intrathecal injection (Hurst, 1932).

Midbrain and basal ganglia These areas may show little else than focal and marked perivascular infiltrations

Cortex and cerebellum. Meningitis and focal and perivascular infiltration occur somewhat irregularly, nerve cell degeneration is only common in the motor area Usually, therefore, the changes in these areas are slight, but Brodie (1934 *d*) has recorded an autopsy on a monkey injected intracerebrally where the cerebral cortex and parts of the cerebellum showed a considerably severer reaction than usual. Burnet, Jackson, and Robertson (1939 *b*) also found changes in the motor area irrespective of the route of inoculation.

Spinal ganglia. Changes have been described in the neurons by Hosselet and Erber (1937), the chondriome becomes granular and eventually disappears, while the Nissl bodies degenerate.

Inclusion bodies have been found by certain authors, both in experimental and

to 4 μ in diameter, and may be surrounded by an unstained halo, as many as 10 may be present in any one nucleus, they do not give the Feulgen reaction and are not doubly refractile to polarized light. It is probable that these inclusions represent nucleolar extrusions

Micro-incineration studies These studies have been carried out by Patton (1933–4, 1934) The spinal cords of monkeys injected intracerebrally were removed at varying periods of clinical involvement Some sections were stained by the usual methods, and others were micro-incinerated (see Ch X). The large anterior horn cells were carefully examined, and with the progress of the infection were seen to undergo 3 definite changes

(*a*) *Edema* Ordinary HE sections showed chromatolysis, the nucleus, at first swollen, later became shrunken and excentric, and the chromatin showed peripheral margination Intranuclear inclusions varying up to 3 to 4 μ in diameter were found, sometimes as numerous as 10 per cell Micro-incineration of similar cells showed a progressive diminution in the amount of mineral ash The inclusions yielded a small quantity of ash

(*b*) *Increased mineral ash* No longer did the nucleus and cytoplasm show approximately parallel changes, for in this stage one might be considerably more degenerated than the other HE sections showed the cell to have become vacuolated and hyperchromic, with a granular cytoplasm and contracted nucleus, neuronophagia might be present

Micro-incinerated cells showed a most striking increase in the cytoplasmic ash, corresponding to the granularity found in the HE sections When neuronophagia occurred, the nerve cells

The Neuromuscular Mechanism

Carey (1943, 1944) examined the neuromuscular mechanism. The earliest changes were hyperemia and perivascular infiltration of the intramuscular blood vessels. This hyperemia was noted in weakened but nonparalyzed muscles, prior to alteration in motor end plates. On the first day of paralysis, some end plates were retracted and some hypertrophied and granular. About 20 per cent. of the motor plates were absent in paralyzed muscle on the first day, and within 2–4 days 50 per cent. had disappeared

From 1–4 days after the onset of paralysis, masses of axonic substance, stained with gold, were found in close relationship to the degenerating tree of innervation The degeneration appeared to begin in the motor end plates, and then extended in a centripetal direction through the epilemmal axons. Carey advanced the hypothesis that *the changes observed in the neuromuscular mechanism in the early stages are* the result of abnormal excitation of the secretory mechanism of the motor end-plates resulting in exhaustion of the gold-staining axonic substance, leading to denervation at the myoneural junction.

The Chronic Stage

There have been few reports of histological examinations in monkeys which have survived a typical attack of poliomyelitis, Warburg (1931) has, however, contributed an important paper on the subject, reviewing previous work but more particularly reporting personal observations. The most important finding was that inflammatory changes might still be present, indicating that the infection was active despite apparent recovery. Degeneration of nerve cells and perivascular infiltrations were the evidences of infection, while microgliosis and astrocytosis indicated repair.

CHAPTER LXXXV

INFECTION OF ANIMALS OTHER THAN THE MONKEY

COTTON RATS

THE MANAGEMENT of cotton rat colonies presents some difficulties and has been

Certain strains of virus have been adapted to this animal, and most work has been done with the Lansing strain adapted to the eastern cotton rat, *Sigmodon hispidus hispidus* by Armstrong (1939 *a, b*, 1941, Lillie and Armstrong, 1940 *a, b*). The infected animal develops roughened fur, jumps when agitated, shows flaccid paralysis, and dies within 2–4 days of the appearance of symptoms. It is most susceptible to intracerebral injection, but according to Weaver (1944, 1945, 1946 *a, b*), it can also be infected by various peripheral routes. Infection *in utero* or by milk does not occur (Weaver and Steiner, 1944).

Histologically, the changes are those of polioencephalitis, similar in characteristics and distribution to those seen in man and monkey (Lillie and Armstrong, 1940 *a, b*) The earliest lesions occur in the cord, the severest reaction is in the medulla and pons; well-marked lesions also occur in the cerebellar roof nuclei and midbrain The cerebral cortex is relatively little involved The nerve cells show necrosis, and there is polymorph infiltration and neuronophagia, there is also focal and diffuse cellular gliosis, swelling of the vascular endothelium, and perivascular

insing strain also infects *S*

partial inanition, influenced

5, 1946 *a, b*). Female cotton rats, or rats deficient in vitamin A, were especially susceptible to paralysis when virus was given by the intratonsillar or other peripheral route (Weaver, 1946 *a, b*).

The Flexner MV and the Phila strains can produce paralysis in cotton rats (Toomey and Takacs, 1940 *c*, 1941 *a, b, c*, Toomey, Frohring, and Takacs, 1943).

The SK strain was adapted to cotton rats after isolation in monkeys, and at first caused an inapparent infection (Jungeblut and Sanders, 1940 *a*).

MICE

Work with Monkey-Pathogenic Strains

Many workers failed to adapt monke
Lewis, 1910 *a, c*, Kolmer and Rule, 1
Harrison, 1934–5, Vieuchange, 1936 *b*, I
1940 *b*, Paraschivesco and Papazolu, 194
and Hudson, 1943) A number of other
seemed suggestive, but in view of the typical changes now known to be produced by murine strains, it is doubtful whether they actually succeeded in adapting virus to the mouse (Nungester, 1932–3; Weil, 1932–3; Brodie, Goldberg, and Stanley, 1935, Toomey and Phelps, 1935–6).

The following strains of virus can be propagated in mice Lansing, MEF1, MM, SK, Y-SK, Ph, and Theiler's virus According to the strain, the appearances are

[1] References are appended at the conclusion of Ch. LXXXVIII, p 1026 et seq.

The Neuromuscular Mechanism

Carey (1943, 1944) examined the neuromuscular mechanism The earliest changes were hyperemia and perivascular infiltration of the intramuscular blood vessels. This hyperemia was noted in weakened but nonparalyzed muscles, prior to alteration in motor end plates. On the first day of paralysis, some end plates were retracted and some hypertrophied and granular. About 20 per cent. of the motor plates were absent in paralyzed muscle on the first day, and within 2–4 days 50 per cent. had disappeared.

From 1–4 days after the onset of paralysis, masses of axonic substance, stained with gold, were found in close relationship to the degenerating tree of innervation The degeneration appeared to begin in the motor end plates, and then extended in a centripetal direction through the epilemmal axons. Carey advanced the hypothesis that the changes observed in the neuromuscular mechanism in the early stages are the result of abnormal excitation of the secretory mechanism of the motor end-plates resulting in exhaustion of the gold-staining axonic substance, leading to denervation at the myoneural junction

The Chronic Stage

There have been few reports of histological examinations in monkeys which have survived a typical attack of poliomyelitis, Warburg (1931) has, however, contributed an important paper on the subject, reviewing previous work but more particularly reporting personal observations. The most important finding was that
...on was active
...r infiltrations
...icated repair.

deficient animals surviving infection may become paralyzed when given adequate thiamine, after a prolonged incubation (Rasmussen *et al.*, 1944).

A similar, but less marked, increased resistance is noted in mice subjected to restriction in calories only (Foster *et al.*, 1943, 1944 *a*, *b*, Rasmussen *et al.*, 1944).

As regards riboflavin, mice deficient in this factor show a slightly greater resistance than controls to the Lansing strain (Rasmussen, Waisman, and Lichstein, 1944).

Deficiencies in pyridoxine, inositol, and biotin do not appear to influence susceptibility to Lansing or Theiler strains (Lichstein *et al.*, 1945)

Mice fed a diet deficient only in calcium pantothenate show a definitely increased resistance to Theiler's virus, but practically none to the Lansing strain (Lichstein *et al*, 1944).

Endocrines. Infected mice treated with thiouracil invariably succumb earlier than controls, whereas those treated with thyroid extract show incubation periods longer than controls (Holtman, 1946 *b*).

As regards estrogens, mice treated with alpha-estradiol dipropionate or diethylstilbestrol show an increased resistance to the mouse-hamster virus inoculated nasally, but not when it is injected peritoneally (Foley and Aycock, 1945), they could not demonstrate increased resistance to Lansing virus inoculated cerebrally.

Temperature. Mice acclimatized to a temperature of 13° C. were found to develop symptoms on intracerebral injection after 11 days, whereas with animals acclimatized to 32° C the symptoms came on in 5 days (Holtman, 1946 *a*).

In apparent contradiction, it was found that the incubation period of the disease in young mice inoculated intracerebrally with the SK strain in standard dose was considerably lengthened in the summer months (Jungeblut, Sanders, and Feiner, 1942).

Chemotherapy in Mice

A number of sulfonamides and sulfones has been tested in infection of mice with the Lansing strain and found to be ineffective (Coggeshall and Maier, 1942; Kolmer and Rule, 1942, Levaditi, 1942 *b*). Kramer, Geer, and Szobel (1944) found 190 compounds useless in modifying the course of infection with the Lansing strain Potassium chlorate had no effect in mice infected with the Lansing strain (Levaditi, 1942 *b*) Anesthetization with ether after infection was also ineffective (Sulkin, Zarafonetis, and Goth, 1946)

About the only promising results in chemotherapeutic experiments are those of Wood and Rusoff (1945). Using the MM strain injected intraperitoneally, they found that intraperitoneal injections of trypan red, brilliant vital red, and Congo red lowered the incidence of infection (Congo red also lowered the incidence of infection in cotton rats)

Neoarsphenamine had a slight effect in murine infections (SK and other strains), the effect was antagonized by cysteine and glutathione, fuadin and sulfapyridine enhanced the effect very slightly (McKinstry and Reading, 1945)

GUINEA-PIGS

The majority of workers has found these animals insusceptible to monkey-pathogenic strains (Flexner and Lewis, 1910 *a*, *c*, Stimson, 1918, Kolmer and Rule, 1933–4 *a*, Brodie, 1934–5 *c*, Woolpert and Harrison, 1934–5, Kolmer, Rule, and Werner, 1937, Yen and Hsu, 1941, Schwab, Woolpert, and Hudson, 1943) Chor (1933) found that injection in splenectomized animals gave general lymphoid hyperplasia, fever, and death within 2 weeks, the lesions were not suggestive of poliomyelitis Guinea-pig fetuses could not be infected (Schwab, Woolpert, and Hudson, 1943)

After 70 transfers in mice, the SK strain developed an increased pathogenicity for guinea-pigs (Jungeblut and Sanders, 1941) A fixed strain of cavian virus was

those of encephalitis or flaccid paralysis, the incubation period also varies with the strain.

Features of Infection with Murine Strains

The Lansing strain has been particularly studied in mice (Lillie and Armstrong, 1940 *b*, Levaditi, 1942 *b*; Smith, 1943 *a*, Vieuchange, 1945, 1946). Animals are usually infected intracerebrally, but may develop infection also by the intraperitoneal route Levaditi could not infect mice intranasally, intradermally, by the sciatic nerve, or by the mouth The incubation period is from 2–92 days, but is usually 4–14 days The animals develop a fatal paralysis, but some may die without paralysis. If passage material is mixed with autolyzed mouse brain, the incubation period is said to be considerably reduced (Milzer and Byrd, 1947).

The histological appearances are similar in character and distribution to those seen in cotton rats infected with the same strain (see p. 995), monkeys, or human beings (Stefanopoulo, Duvolon, and Étévé, 1942, Ehrich and Foster, 1944, Foster and Ehrich, 1944, Vieuchange, 1945, 1946).

The content of adenosine triphosphate is greatly increased in the brain, phosphocreatine and residual organic phosphate are markedly decreased (Kabat, 1944)

The distribution of virus after intracerebral injection has been studied Virus can be found in the blood and spleen for 1–2 hours after inoculation (Smith, 1943 *b*). Mice which develop paralysis within 5 days after intracerebral inoculation show as much virus in the brain as in the cord and medulla, after 5 days little virus is isolated from the brain, parts of the cord and medulla of mice becoming paralyzed up to 4 weeks after inoculation contain as much virus as do specimens obtained in the first 5 days (Herrarte and Pearson, 1943).

Half an hour after intraperitoneal injection, virus can be recovered from the blood and spleen, it persists in the blood for 7 and the spleen for 12 hours (Smith, 1943 *b*).

The SK strain has also been studied in mice. When adapting the strain from cotton rats, the first few passages caused an inapparent infection (Jungeblut and Sanders, 1940 *a*).

After over 200 serial intracerebral passages, this strain increased in virulence from a titer of 1/1 million to not less than 1/1 billion (Jungeblut, Sanders, and Feiner, 1942) Bourdillon and Moore (1942) found the infectivity of a standard intracerebral inoculum of 0 03 c.c to be from 10^{-7} to 10^{-8}.

Young mice are more susceptible to peripheral inoculation than older animals, but intracerebral injection is equally fatal in young and old animals (Jungeblut, Sanders, and Feiner, 1942).

The SK strain is present in the brain, cord, blood, spleen, liver, and adrenals of infected mice (Jungeblut and Sanders, 1940 *a*)

The SK strain also attacks the anterior horn cells, and with an increase in virulence there is an increased affinity for the cerebral tissues (Wolf, 1942)

The *MM strain* has similar properties to the SK, and kills mice within a few days

Influence of Various Factors on the Susceptibility of Mice

Strain of mouse Cross-bred mice (Swiss white mother, wild gray father) have been found more susceptible to the Lansing strain than pure-bred white mice (Holtman, 1947).

Nutrition. Thiamine-deficient mice have been shown to be more resistant than usual, particularly as regards the incidence of paralysis, to the Lansing or Theiler viruses, vice versa, the incidence of paralysis is greater in mice on a high thiamine diet than in those on a low diet (Foster *et al*, 1942, Rasmussen *et al*, 1944, Waisman *et al.*, 1945). This resistance is only partly explicable by the accumulation of pyruvate or other metabolites (Waisman *et al*, 1945). In some instances, thiamine-

and Rule, 1933–4 *a*, Brodie, 1934–5 *c*; Woolpert and Harrison, 1934–5; Swan, 1942), the bush rat, *Cricetomys gambianus* (Findlay, Anderson, and Haggie, 1946), *Microtus*, *Neotoma*, *Peromyscus*, *Perognathus*, *Dipodymus* (Kessel and Stimpert, 1940); horses, calves, goats, pigs, sheep, dogs, and cats (Flexner and Lewis, 1910 *a*, *c*), pigeons and chickens (Kolmer, Rule, and Werner, 1937, Schwab, Woolpert, and Hudson, 1943); hedgehogs and agoutis (Grossman and Kramer, 1937–8) Fetuses of white mice and white rats could not be infected (Schwab, Woolpert, and Hudson, 1943).

The Flexner MV strain adapted to cotton rats did not infect white rats even when suffering from vitamin B_1 deficiency (Toomey, Frohring, and Takacs, 1943).

Chicks injected intracerebrally with the rodent-adapted MM strain harbored virus and developed antibodies, but there was no definite adaptation (Brutsaert, Jungeblut, and Knox, 1946 *a*).

Jaculus jaculus and *Arvicanthis barbarus* were not susceptible to Lansing virus (Durand, 1945).

The Lansing strain did not infect ground squirrels *Citellus tridecem lineatus* and *C. richardsonii*

obtained by passage in guinea-pigs (Jungeblut, Feiner, and Sanders, 1942) The animals develop flaccid paralysis and show typical lesions of the anterior horn cells They are susceptible to murine SK virus by intracerebral, intravenous, intraperitoneal, and subcutaneous inoculation, but the cavian strain produces paralysis only on intracerebral or intravenous inoculation. This cavian passage virus produced only mild lesions in the monkey.

The SK strain shows a characteristic attack on the anterior horn cells and the features resemble those of the disease in man (Jungeblut and Sanders, 1941; Wolf, 1942).

HAMSTERS

The Chinese hamster was not found to be susceptible to a monkey pathogenic strain (Yen and Hsu, 1941). Young hamsters are susceptible to the M-hamster virus inoculated intraperitoneally, and develop paralysis within 5 days (Dalldorf and Whitney, 1943).

The Lansing strain could be passed intracerebrally in the Syrian hamster, and a fatal paralysis developed, a few survivors showed muscular atrophy and contracture The pathological features were typical of poliomyelitis (Plotz, Reagan, and Hamilton, 1942). Durand (1945) also found the Syrian hamster susceptible after an incubation of 4–7 days, fatal paralysis developed, and conjunctivitis might be present.

OTHER SUSCEPTIBLE RODENTS

The Lansing strain infects a number of other rodents *Microtus* (Kessel and Stimpert, 1940), *Neotoma* (Kessel and Stimpert, 1940), *Peromyscus* (Kessel and Stimpert, 1940, Gordon, 1945 *a*), *Ondatra zibethcus* (muskrats) (Gordon, 1945 *a*).

Adult specimens of *Meriones shawi* develop symptoms in 3–13 days after intracerebral inoculation of the Lansing strain, paralysis often occurring (Durand, 1945). In very young animals, subcutaneous, intraperitoneal, or nasal inoculation proves positive Durand found the following to be less regularly susceptible *Psammomys obesus, Gerbillus hirtipes, G atoni, Dipodillus campestris (quadrimaculatus), D dodsoni*

OTHER SUSCEPTIBLE ANIMALS

Frauchiger and Hoffmann (1938) claimed to have produced paralysis and muscular atrophy in a cow inoculated with human material.

Ferrets were found to be insusceptible by Kolmer, Rule, and Werner (1937), but Patŏcka (1941) found one particular strain that produced degenerative changes in the anterior horn cells.

RABBITS

Certain workers have claimed that monkey-pathogenic strains can be transmitted (Dahm, 1909. Krause and Meinicke, 1909, 1910, Levaditi and Landsteiner, 1910 *a*, Ceccaldi, 1943) Other workers have not been able to demonstrate any specific evidence of infection with such strains (Flexner and Lewis, 1910 *a*, *c*, Stimson, 1918, Kolmer and Rule, 1933–4 *a*, Brodie, 1934–5 *c*, Kolmer, Rule, and Werner, 1937, Toomey and Takacs, 1940 *a*, Yen and Hsu, 1941, Kempf, Pierce, and Soule, 1941, Schwab, Woolpert, and Hudson, 1943, Toomey, Pilcher, and Rossman, 1943) Rabbit fetuses could not be infected (Schwab, Woolpert, and Hudson, 1943)

The murine SK virus is not pathogenic to rabbits (Jungeblut and Sanders, 1940 *a*).

INSUSCEPTIBLE RODENTS AND OTHER ANIMALS

The following animals have been found insusceptible to monkey-pathogenic strains rats and jerboa mice (Flexner and Lewis, 1910 *a*, *c*, Stimson, 1918, Kolmer

(c) In 1933, Gildemeister reported that he had secured growth of the virus in tissue culture, the medium, consisting of Tyrode's solution, monkey serum, and chick embryo brains, was incubated at 37° C. in Carrel flasks Poliomyelitis developed in monkeys inoculated with the 8th subculture. Kast and Kolmer (1937) were not, however, able to confirm

(d) Using human embryos (3 to 4 months old) obtained by cesarean section and cultured in Tyrode's solution, Sabin and Olitsky (1936 b) also were able to obtain growth of the virus Typical infection was produced in monkeys by 1 c c. of the 6th subculture which represented a dilution of the original inoculum of 1:1,000,000

(e) More recently the SK strain has been cultivated. Jungeblut and Sanders (1940 a) obtained growth in embryonic mouse brain in ox serum ultrafiltrate. In further studies they found that the optimum pH was 7 3-7 6 (Sanders and Jungeblut, 1942) On prolonged subculture, the virus showed a loss of infectivity for mice on peripheral inoculation, although the potency by the intracerebral route remained constant. The SK strain can be titrated *in vitro* in embryonic mouse brain (Huang, 1943).

CULTIVATION IN EGGS

Monkey-pathogenic strains have not been cultivated on the chorio-allantois (Burnet, 1935, Kast and Kolmer, 1937). Gard (1943 c) has claimed that the virus may propagate in young embryos and invade the brain.

The MM rodent-adapted strain could not be propagated by the allantoic route (Brutsaert, Jungeblut, and Knox, 1946 a). The SK and Lansing strain have been propagated by the chorio-allantoic and yolk sac routes and invade viscera (Schultz and Enright, 1946).

REACTION TO PHYSICAL AGENTS

The influence of pH on the infectivity of the Lansing strain in mice has been investigated by Hammon and Izumi (1941) who found that a definite quantity of virus can be rendered several times more infective at pH 4 than 7. Faber and Dong (1946) found this strain was completely inactivated at pH 1 0 in 5 minutes, at pH 2.0 partial inactivation began at 2 hours and was complete at 4 hours. At pH 3 0 and 4 0 there was no inactivation at 4 hours The virus is electronegatively charged (Olitsky, Rhoads, and Long, 1929) Bourdillon (1943-4 a) investigated the electrophoretic mobility of the unpurified SK strain X-rays have no definite effect on the virus (Lenz and Jungeblut, 1931-2) Monkey and mouse strains are inactivated rapidly by ultraviolet light, probably in less than 1 second (Toomey, 1937 b, Jungeblut, 1937-8, Levaditi, 1942 d, Milzer, Oppenheimer, and Levinson, 1944, 1945) Sunlight, especially in the presence of eosin, also has a destructive effect (Flexner, 1916, Amoss, 1928)

Methylene blue solutions (1 50,000 to 1 100,000) inactivate the virus when exposed to light (Rosenbloom, Hoskwith, and Kramer, 1937-8)

Supersonic vibrations completely destroy the virus (Kasahara *et al*, 1938), material so treated is antigenic (Keeser, 1939) Homogenization of infected tissue increases its activity (Scherp and Chambers, 1936-7)

Numerous observations have been made on the effect of heat on the virus (see Shaughnessy, Harmon, and Gordon, 1930, for bibliography) The general opinion of these workers is that 55° C destroys in up to half an hour Lawson and Melnick (1947) have carried out experiments with rodent-pathogenic strains, using infected nerve tissue, infectivity was reduced by 95 per cent in 30 minutes at 45° C., but over 60° C was required for complete inactivation Milk exerted a protective effect on virus in nerve tissue, virus withstanding 5-10° C. extra The virus survives for at least 50 days at +4° C (Flexner and Lewis, 1910 c)

After desiccation *in vacuo*, the virus probably survives for at least a month (Landsteiner and Levaditi, 1909 b, Romer and Joseph, 1910 b). It retains its virulence

CHAPTER LXXXVI

SOME OTHER PROPERTIES OF POLIOMYELITIS VIRUSES

MORPHOLOGY

COLES (1939)[1] claimed to have identified elementary body-like structures, but they are too small to be seen with ordinary microscopic equipment

Inclusion bodies have been described in the nuclei of infected cells in man and monkey, these have been subjected to micro-incineration, the Feulgen test, and [illegible] they represent nucleolar extrusions [illegible] been taken by Jungeblut and Bour-[illegible]asuring 25–30 mμ in purified preparations (see also Loring, 1947). In unpurified preparations of tissue cultures long thread-like structures up to 5000 mμ were seen. Loring, Marton, and Schwerdt (1946) examined purified preparations of the Lansing strain, and found spherical or slightly asymmetrical particles of 12–34 mμ, no threads were seen

Rod-shaped particles have been seen by Gard (1943 *a*, *b*) and Melnick (1944 *a*) in stools and nervous tissue. Gard, in his studies on the purification of Theiler's virus (see p. 1004), demonstrated rod-shaped particles in purified preparations, structures about 15 mμ by 115 mμ were seen also in material from human cords, and in the stools of healthy as well as infected humans

FILTRATION AND CENTRIFUGATION

Monkey-pathogenic strains have been found to pass through the following filters Chamberland L5, Berkefeld V and N, and with difficulty through W (Flexner and Lewis, 1909 *c*, 1910 *c*, Landsteiner and Levaditi, 1909 *a*, *b*, Amoss, 1928), Seitz filters can also be used.

Monkey-pathogenic strains measure 8–17 mμ by ultrafiltration (Krueger and Schultz, 1928–9, Clifton, Schultz, and Gebhardt, 1931, Theiler and Bauer, 1934, Elford, Galloway, and Perdrau, 1935, Levaditi *et al*, 1936).

The SK strain measures 10–15 mμ (Sanders and Jungeblut, 1942) Levaditi (1942 *c*) obtained a larger figure for the Lansing strain, but probably for technical reasons

Monkey-pathogenic virus can be sedimented in the ultracentrifuge (Schultz and Raffel, 1937–8). The SK strain showed a sedimentation constant around 100 S, with a molecular weight of about 10 million (Bourdillon and Moore, 1942, Bourdillon, 1943–4 *a*). The Lansing strain was found to be sedimented after 4 hours at *18,000 r p m (Silverberg, 1945)*

TISSUE CULTIVATION

Numerous attempts have been made to cultivate monkey-pathogenic strains

(*a*) Early work by Levaditi (1913 *a*, *b*), using the method of Marinesco and Minea (1912), showed that virus in infected spinal ganglia of monkeys conserved its virulence after several passages in monkey plasma

(*b*) Later, work was carried out by Eberson in which suggestive evidence of growth was obtained (Eberson, 1931–2, 1932, 1936, Eberson and Mossmann, 1932–3). The medium (VB), which probably contained living cells, consisted of sheep brain in veal broth After some days turbidity developed, and small elementary bodies measuring up to 0 2 μ in diameter were found Infection could be transmitted to monkeys even after a dozen subcultures (representing a virus dilution of 2×10^{-27}).

[1] References are appended at the conclusion of Ch LXXXVIII p 1026 et seq

PURIFICATION AND NATURE OF THE VIRUS

A number of earlier workers achieved some success in their attempts to purify and concentrate poliomyelitis virus in monkey tissue. The methods used included filtration (Clark, Ainsworth, and Kindschi, 1933–4), adsorption to, and elution from, alumina gel, and concentration *in vacuo* (Sabin, 1930–1, 1932), adsorption to, and elution from, aluminum hydroxide (Schaeffer and Brebner, 1933), half-saturation with ammonium sulfate (Clark, Schindler, and Roberts, 1930), precipitation with safranine (Howitt, 1930–1) Brown and Kolmer (1937–8) attempted unsuc-

orkers has succeeded
weight, probably of
and mouse-infected
order. Most workers

have started with nervous tissue and made use of ether, protein precipitants, and differential centrifugation

Method of Clark, Rasmussen, and White (1941)

Clark, Rasmussen, and White (1941), using ether-extracted monkey tissue, confirmed earlier observations that half-saturation with ammonium sulfate brings down almost all the virus, especially at pH 4 5. The virus appeared to come down with the euglobulin and pseudoglobulin fractions. Virus was further concentrated from the sediment of the purified suspension by repeated ultracentrifugation and distillation *in vacuo*

Method of Bourdillon and Moore

Bourdillon and Moore (1942) used the SK strain The method of concentration in-

dillon (1943–4 *a*, *b*) reported on various constants and on the rate of thermal inactivation of purified material.

Method of Racker (1942)

Racker worked with infected mouse brain tissue The method involved ether treatment, adjustment of pH to 4 0, centrifugation, precipitation with ammonium sulfate, and dialysis After treatment with acetic acid, a crystalline material was obtained, highly infective for mice He did not claim that this material was the virus, as the infectivity factor might merely have been adsorbed thereto

Method of Herrarte and Francis

These workers (1943) purified the Lansing strain by adding protein precipitants to suspensions of brain and cord of mice Using ether and centrifugation, they found nearly all the virus was present in a solid layer under the ether. The virus could be readily dissolved in alkaline buffer to yield a clear material

Method of Loring and Schwerdt

ey found that the purified form of the MVA virus

In 1946, Loring and Schwerdt obtained a material of high molecular weight from the nervous tissue of cotton rats infected with the Lansing strain Etherization and differential centrifugation were employed. The yield after a third cycle of centrifugation was 0 1 to

The same procedures
only 0 02–0 01 mg The
as strongly in favor of
the virus particles to

after desiccation over phosphorus pentoxide for at least 24 days (Landsteiner, Levaditi, and Pastia, 1911 *a*). Melnick (1946 *c*) found that 2 mouse-adapted strains and Theiler's virus maintained their original infectivity for 12 months in the frozen state at − 70° C or − 20° C

REACTION TO CHEMICAL AGENTS

Poliomyelitis virus is glycerol-resistant (e g, Flexner and Lewis, 1909 *c*, Landsteiner and Levaditi, 1909 *a*, *b*, 1910; Flexner, Clark, and Amoss, 1914 *b*, Flexner and Amoss, 1917 *c*, Rhoads, 1929) In 33 to 50 per cent. glycerol it can survive with comparatively little loss of virulence for at least 6 to 8 years (Flexner and Amoss, 1917 *c*; Rhoads, 1929) Moore and Kessel (1943) found that each 7–9 months of storage tended to reduce the titer to the next lower tenfold dilution, but the *severity of the illness was not affected It is relatively ether-resistant* (see, e g, Sulkin and Zarafonetis, 1947).

A large number of compounds has been found to destroy or inhibit monkey strains *in vitro*. citrate (Rhoads, 1931 *a*), potassium permanganate, hydrogen peroxide, menthol, salol, boric acid (Levaditi and Landsteiner, 1910 *d*, *e*), strong urea solution (Mackay and Schroeder, 1936–7); formalin vapor (Romer and Joseph, *1910 b*), *isamine blue, to a slight extent (Hornus and Haber, 1934), chrysoidin* Y, Congo red 4 B, copper sulfate, hexylresorcinol, mercuric chloride, mercurochrome, Unna's polychrome methylene blue, oxyquinoline sulfate, potassium hydroxide, and potassium permanganate (Schultz and Robinson, 1942). Synthetic ascorbic acid was found to render virus noninfective (Jungeblut, 1939) The virus is inactivated by adsorption to cholesterol (Toomey, 1937 *e*), ergosterol, and vitamin D (Toomey and Takacs, 1938 *c*). The virus is relatively resistant to salicylate (Cooke and Best, 1941), and cetamium (Toomey and Takacs, 1945)

The chemotherapy of monkeys is discussed on page 987 and of mice on page 997

REACTION TO BIOLOGICAL AGENTS

Normal testicular extracts produce a marked loss of virulence when mixed with virus *in vitro* (Jungeblut, 1932).

The virus is not destroyed by bile (Landsteiner, Levaditi, and Pastia, 1911 *a*, Levaditi, Kling, and Lépine, 1931) or trypsin (Faber and Dong, 1946) It can survive the gastro-intestinal secretions for at least 2 hours *(Flexner, Clark, and* Dochez, 1912), however this probably depends on pH The virus inactivating agent (VIA) present in normal human nasal secretion, acting powerfully on influenza virus, *has a slight action on the MV strain (Burnet, Lush, and Jackson, 1939)* Allen and Clark (1941) also studied VIA in man, in the naturally resistant calf, they did not find that an extract of the olfactory mucosa neutralized virus

The virus can survive in butter for at least 3 months at −2° C (Kling, *Levaditi*, and Lépine, 1931), in milk for at least 31 days at room temperature (Landsteiner, Levaditi, and Pastia, 1911 *a*), in water for about 3 months at room temperature (Landsteiner, Levaditi, and Pastia, 1911 *a*, Kling, Levaditi, and Lépine, 1929)

ANAEROBIC GLYCOLYSIS OF INFECTED BRAIN

Brodie and Wortis (1934) found no great alteration from the normal when investigating the respiratory mechanism of excised brain and cord from an infected monkey A number of workers has investigated the conditions underlying the *metabolism and anaerobic glycolysis of mouse brains* infected with the Lansing and similar strains (Racker and Kabat, 1942, Kabat *et al.*, 1943, Nickle and Kabat, 1944, Utter, Reiner, and Wood, 1945, Wood, Rusoff, and Reiner, 1945) Purified preparations are said to inhibit glycolysis when added to homogenates of normal mouse brain (Racker and Krimsky, 1946)

CHAPTER LXXXVII

-ir between antiserum
-940) could find

IMMUNITY IN POLIOMYELITIS. ACADEMIC AND EXPERIMENTAL ASPECTS

ANTIGEN-ANTIBODY REACTIONS

THE ANTIBODY most readily demonstrable in poliomyelitis is the virus neutralizing antibody, although certain other antibody effects can be shown.

VIRUS NEUTRALIZATION

Virus neutralization tests in monkeys.

Until recently, poliomyelitis antibody could be demonstrated only by its ability to neutralize the infectivity of virus on inoculation in monkeys. The expense involved in obtaining a satisfactory result seriously restricted the usefulness of this type of test, which can now be replaced by titration in mice (see below)

Tests in monkeys should be quantitative. For example, 1000 m c p. doses of virus can be tested with varying dilutions of serum (Madsen and Jensen, 1936,[1] Eagles, Jensen, and Henningsen, 1937). Kolmer and Rule (1935 *a*) recommended a constant amount of serum with varying quantities of virus

In the majority of observations, monkey passage virus has been used as antigen, but it would appear preferable to use a local recently isolated strain, in view of

ody may

the test

nonkeys.

Burnet, Jackson, and Robertson (1939 *b*) have recommended the use of cynomolgus animals, using intracerebral or intra-ocular injections, rhesus monkeys can also be injected intra-ocularly (1939 *a*).

Work of Schaeffer and Muckenfuss.

Schaeffer and Muckenfuss (1940) have published a valuable monograph on the neutralization test in monkeys. From their review of the literature, they conclude that the technique used in the past has not conduced to accurate results Many of the published results, especially when a single monkey has been used per sample, have been of little or no value The test is unsuitable for quantitative studies, such as detecting antigenic differences between strains, but is of value in qualitative studies such as epidemiological surveys.

In their own experimental work, designed to improve the test, and reduce the chances of inaccuracy, they used the following basic technique

As a source of virus, they employed the pooled mixture of about 50 monkeys' spinal cords removed at the height of paralysis (MV strain). The cords were then minced mechanically, and placed in a sterile flask with 50 per cent glycerin, and shaken for 12 hours The material was stored at −20° C till required A 5 per cent. suspension of pooled cords was prepared, centrifuged at 2,000 r p m for 15 minutes, and the supernatant (with or without filtration) used as virus

Equal portions of virus and serum (neat or diluted) were placed in test tubes, mixed, and transferred to a fresh set of tubes, held at 37° C for one hour, placed in the refrigerator overnight, and then incubated at 37° C for another hour the next morning The volume of incubated mixture generally inoculated was 1 c c. A 1 c c tuberculin syringe was used, and a ¼" 26 gage needle The inoculation was made 1 cm to the right of the

[1] References are appended at the conclusion of Ch. LXXXVIII, p 1026 et seq

Method of Melnick

Melnick (1943 *a*) concentrated infected stool material by differential ultracentrifugation and etherization He isolated a macromolecular fraction from human, monkey, and chimpanzee stools. Later (1946 *a*, 1947) he introduced the Sharples instrument, he has used a special technique for isolating virus from sewage (see p 963).

Work of Gard

Gard (1943 *a*) has carried out extensive studies on the purification of Theiler's and human strains, using the method of concentration essentially the same as that described on page 931 (see also 1943 *b*). He isolated from mouse brains infected with Theiler's virus a substance identical with the virus protein. The substance was present in all active specimens adequately concentrated, but absent in concentrates from normal mouse brains The preparations, representing 1 5 × 10^{-4} per cent. of the original material, retained 30 per cent. of the total virus content. The infectivity of the purified substance was thus about 200,000 times that of infected brain The infectivity of different preparations varied proportionally with their content of virus protein The purest preparations were homogeneous in the ultracentrifuge, and had a sedimentation constant equal to that of the virus The size (i e., breadth) of the virus rods was found to be 10–15 mμ by ultrafiltration The molecules were rod-shaped or filamentous, the width being found to be 12–13 mμ by sedimentation or diffusion data, or 15 mμ by the electron microscope Statistical analysis of titration experiments suggested that most of the virus particles appeared in larger aggregates which probably dissociated on dilution Sedimentation and diffusion experiments disclosed a certain inhomogeneity of the presumed virus protein, indicating that the particles in reality were aggregates of smaller units end to end This was confirmed in electron micrographs, where the length of the elementary particles was estimated at about 115 mμ Most fibers had a length of about 1 μ and corresponded to 8–9 particles The molecular weight of the protein was calculated to be about 57,000,000, referring to aggregates of about 5 elementary particles

Small amounts of a substance resembling the material considered to be pure mouse virus were recovered from human brain and cord This was not obtained in a pure state, but electron micrographs showed structures of the same size and shape as the mouse virus

Further work was carried out with stools From human stools 3 main components were isolated, one of which resembled closely the substance obtained from infected nervous tissue, and held to be pure virus A pure preparation of this stool component presumably retained all the original infectivity However the stools of healthy persons yielded a similar substance

The feces of normal mice yielded a component of the same type The component from young animals proved infective, but not that from older animals Similar noninfective components were isolated from the feces of pigs and wild brown rats

Intestinal protein could not be distinguished from virus protein by sedimentation data or electron micrographs It was composed of molecules of the same size and shape as those of the virus In infective specimens, the viral activity was concentrated along with this protein

The diffusion constant (D_{20}) of the substance derived from infected mouse brains was 0 32 × 10^{-7}, while that of the intestinal components of man, white mouse, and brown rat was 0 11 × 10^{-7} From the diffusion and sedimentation constants, assuming cylindrical and nonhydrated molecules, the following figures were calculated nervous material—molecular weight 57 × 10^6, particle size 12 5 × 580 mw, intestinal material, m w 200 × 10^6, particle size 12 2 × 2150 mμ

A pure preparation of intestinal material of human origin was found to be probably a nucleoprotein

The intestinal proteins were antigenically active in rabbits, and those from man, white mouse, and brown rat were related

It is suggested tentatively that intestinal protein is an avirulent or non-neurotropic variant of poliomyelitis virus It is a normal inhabitant of the intestines, is absorbed and deposited in lymph nodes with the consequent acquisition of the immune state The intestinal protein (virus) is nonpathogenic, but under the influence of exogenous factors, e g, weaning in the mouse, or climatic factors in man, many undergo variation to a neurotropic form

Complement Fixation

Kolmer and Rule (1935 *b*) concluded that fixation may occur between antiserum and monkey virus, but Harrison (1939) and Raffel and Schultz (1940) could find no evidence of this phenomenon.

Precipitation

[illegible]

Allergy

It was found that if virus was injected in the spleen of monkeys immune to poliomyelitis (either by recovery from infection or by vaccination), sudden death occurred (Brebner, 1931–2) Death did not result unless about 7 weeks had elapsed [illegible] lytic attack, That such [illegible] c) reaction was sug- [illegible] mucosae, necrosis of the center of the liver lobules, and hemorrhages in the medulla.

Monkeys which have been injected parenterally on a number of occasions develop a prolonged febrile disturbance 3 to 4 days after intracerebral injection Jungeblut (1931) has suggested that this altered response is indicative of an allergic phenomenon

Miscellaneous Reactions

It has been suggested that colloidal gold solution is precipitated by salt in the presence of poliomyelitis antibody (Eberson, 1930–1; Eberson and Mossmann, 1931–2). Schultz *et al* (1934), however, were unable to distinguish between convalescent and normal sera, the precipitation was nonspecific and appeared to be closely related to the absorption of foodstuffs from the bowel

Some experiments have been performed on the agglutination of sensitized bacteria (Hallauer and Renz, 1945, Roberts, 1945).

ACTIVE IMMUNITY INDUCED BY LIVE VIRUS IN ANIMALS

In Monkeys and Chimpanzees

On recovery from a paralytic attack induced, for example, by intracerebral or intranasal injection, monkeys usually show a marked resistance to a challenge injection of virus, even if given intracerebrally (Flexner and Lewis, 1910 *a*, *c*, Levaditi and Landsteiner, 1910 *a*, Leiner and Wiesner, 1910 *a*, *b*, *c*; Amoss, 1928, Kessel and Stimpert, 1941) The state of resistance probably develops from 7–10 days after the onset of paralysis

In general, the severer the attack, the more marked the subsequent resistant state (Toomey, 1936 *c*, 1938 *a*, 1939 *b*, Moore *et al*, 1942, Moore and Kessel, 1943)

Resistance is more likely to be overcome if the challenge injection is of an heterologous strain, massive doses can also overcome the resistant state (Toomey, 1938 *a*, Kessel and Stimpert, 1941, Howe and Bodian, 1942 *a*)

Challenged animals not completely resistant may develop localized paralysis or nonparalytic attacks

Chimpanzees developing a subclinical attack and excreting virus following dermal inoculation or ingestion of virus resisted a challenge dose of the homologous strain given by the same route (Melnick and Horstmann, 1947).

Toomey and Weaver (1939) reported that monkeys recovered from poliomye-

the coronal suture, and the contents inoculated in the
Melnick (1943 *a*) concentr- ... esia. Young rhesus monkeys of 6–8 lbs weight were
and etherization. He is- ... t 30 days, daily temperatures were taken, all animals

Neutralization tests in mice.

The discovery of human strains of virus transmissible to mice has allowed of titration of antibody in these animals As adequate numbers can be used, more accurate results can be obtained Armstrong (1941) found agreement between titrations in mice and monkeys Mice may be injected intracerebrally with virus-serum mixtures, using the Lansing strain, 8–12 mice per dilution are used, and they should be observed for 21 days (Armstrong, 1941, Harford and Bronfenbrenner, 1941, Hammon and Izumi, 1942 *a*, *b*, Young and Merrell, 1943, Armstrong and Davis, 1945, Brown and Francis, 1945, Olitsky and Findlay, 1946, Morgan, 1947 *a*). The MEF1 strain can also be used (Olitsky and Findlay, 1946).

Neutralization tests in cotton rats.

Cotton rats can be used for the titration of antisera by the intraperitoneal or intracerebral injection of mixtures of serum and the Lansing strain (Hallauer and Renz, 1945).

Effect of antiserum on infectivity of virus.

Poliomyelitis antiserum neutralizes but does not destroy virus *in vitro* Complement is not required for the reaction (Fairbrother, 1930). Active virus can be recovered from neutral mixtures by various procedures Virus has been recovered by cataphoresis (Olitsky, Rhoads, and Long, 1929) Dilution with saline renders neutral mixtures infective (Schultz, Gebhardt, and Bullock, 1930–1, 1931) Schaeffer and Muckenfuss (1938, 1940) found that when long needles were used for the intracerebral injection of apparently neutral mixtures infection resulted, but with short needles the mixture proved noninfective. Neutral mixtures act as antigens in monkeys and stimulate the production of antibodies (Romer and Joseph, 1910 *a*, *b*, Brodie, 1932 *b*, Kramer and Schaeffer, 1933–4, Kramer, Schaeffer, and Park, 1934)

Virus neutralizing properties of tissues.

Normal monkey brain or cord added to virus *in vitro* exerts no neutralizing effect (Jungeblut, 1932) The cords of convalescent monkeys either show no neutralizing action, or at most an irregular one (Landsteiner, Levaditi, and Pastia, 1911 *a*, Jungeblut, 1932).

In Rodents

Guinea-pigs recovered from paralytic or symptomless attacks, induced by the SK strain, are resistant to challenge with the homologous virus (Jungeblut, Feiner, and Sanders, 1942) Cotton rats could be rendered resistant to an intracerebral challenge following the intra-ocular, intratonsillar, intracardiac, intraperitoneal, or subcutaneous administration of virus, administration by other routes was less effective (Weaver, 1946 *a*).

Mice can be rendered resistant to an intracerebral challenge of the Lansing strain by intraperitoneal or subcutaneous injection (Levaditi, 1942 *a*, Kramer and Geer, 1945, Milzer and Byrd, 1947). This refractory state lasts for about 85 days (Levaditi, 1942 *e*)

Sanders and Jungeblut (1942) rendered mice relatively resistant to a mouse-passed strain of the SK virus by the inoculation of tissue cultured virus by peripheral routes. Preparation of mice with estrogen decreased the numbers showing active disease, and increased the numbers becoming immune by subclinical attack (Aycock and Curley, 1947).

ACTIVE IMMUNITY INDUCED IN ANIMALS BY INACTIVATED OR ATTENUATED VACCINES

In Monkeys

Physically or chemically treated virus Attempts have been made to modify the virus so that it retains immunizing properties while losing pathogenicity. Flexner (1935 *b*) concluded that no evidence had been advanced to show that such a result could be obtained.

Virus attenuated by heat at 45° C. for half an hour induced some resistance (Romer, 1912) Desiccated virus has also been employed with some success (Levaditi and Landsteiner, 1910 *b*) Virus inactivated by supersonic vibration has been used by Kasahara (see Paul, 1947 *a*).

Tannin-treated virus failed to immunize monkeys regularly (Olitsky and Cox, 1936). Chloroform-treated virus was also ineffective (Kolmer and Rule, 1934 *a*).

Phenolized vaccines have proved effective, but probably only in preparations where the virus is attenuated and not destroyed (Kraus, 1911, Aycock and Kagan, 1927, Cowie 1934–5, Brodie, 1935 *b*)

Most attention has been paid to formalin and sodium ricinoleate·

Brodie's vaccine It was shown that monkeys could be immunized, so as to withstand even intracerebral injection, by a course of formolized cord given subcutaneously (Erber and Pettit, 1932)

Brodie also found that formalin-treated virus was antigenic (1934 *a*, 1934–5 *a*) Virus was treated with 0 1 per cent. formalin for 16 to 48 hours, and used to immunize children (see p. 1015) Later, Brodie recommended virus inactivated with 0 05 per cent formalin (1935 *a*)

Monkeys can readily be immunized by an injection of 5 c c. of 10 per cent. infective cord treated with formalin, becoming as resistant as monkeys recovered from an attack of poliomyelitis, and developing serum antibodies. Unlike the immunity resulting from injections of active virus, that following formolized virus is not proportionate to the dose used, being optimal after injection of 0 5 gm. of cord (Brodie, 1935 *b*) As regards the activity of Brodie's vaccine, Brodie and Park (1935 *b*) found that 5 c c of virus inactivated by 0.1 per cent. formaldehyde for 8 to 12 hours at 37° C was noninfective Trask and Paul (1936), however, found that 0 1 per cent. formaline did not destroy the virus in 24 hours in the refrigerator.

Kramer (1936 *a*) attempted to immunize monkeys with a vaccine prepared by Brodie's method, even after large loses, antibodies were only rarely developed, and animals succumbed to test injections of 0 01 c c of virus Similar results were obtained by Olitsky and Cox (1936) Thus, at the present, it can hardly be accepted

litis with residual signs again became paralyzed when inoculated with bacterial cultures, the cords did not show changes characteristic of poliomyelitis

The work of Howe and Bodian has shown that whether a rhesus monkey develops a second attack on challenge depends partly on the strain of virus used, and partly on the degree to which the virus disseminated in the CNS on the first exposure. Only limited portions of the CNS may be refractory (Howe and Bodian, 1941 *e, f*; 1942 *a*).

They found that 2 rhesus monkeys convalescent from an intracutaneous and an intracerebral inoculation, respectively, suffered further paralysis after nasal inoculation of an heterologous strain. A third animal convalescent from an intranasal inoculation showed an extension of lesions after the intranasal and intraocular inoculation of an heterologous virus.

Two "spinal" animals, in which the attack of poliomyelitis was limited to an isolated segment of the cord, contracted typical paralysis in the previously uninvaded portions of the CNS following intranasal inoculation of an homologous virus

Four out of 6 convalescent monkeys showed an extension of lesions, without clinical signs, when the homologous virus was inoculated by a new route.

Animals convalescent from a unilateral intranasal inoculation showed evidence of a fresh invasion in the opposite olfactory bulb, but no extension of paralysis, following a second inoculation of homologous virus in the appropriate nostril.

Two animals developed second attacks when a second inoculation of heterologous virus was given, the intranasal route being used on each occasion

Continuing these observations, Bodian and Howe (1945 *b*) found that a chimpanzee recovered from an intracerebral injection sustained a second infection limited to the olfactory bulbs when given virus nasally two weeks later. Another chimpanzee contracted a nonparalytic attack after administration of virus by a stomach tube. When infected orally 9 months later, the animal developed a paralysis of the facial nerve only.

Resistance can also be induced by *injections of live virus*, preferably repeated, without the development of obvious clinical manifestations Refined products have not been found to be significantly more antigenic than cruder preparations (Gordon, 1932–6, Gordon, Harrison, and Hudson, 1935, Kramer, Grossman, and Hoskwith, 1936). Thus virus can be given by the following routes

(*a*) Subcutaneously (Levaditi and Landsteiner, 1910 *c*; Flexner and Lewis, 1910 *c*, Stewart and Rhoads, 1929, Pettit, Erber, and Kolochine, 1932).

(*b*) Intracutaneously (Aycock and Kagan, 1927, Stewart and Rhoads, 1929, Jungeblut and Hazen, 1930–1 *a*, Rhoads, 1930, Brodie, 1932 *b*, Thompson and McKinley, 1934–5); Stimpert and Kessel (1940) found that the immunizing power of different strains varied, and was not related to virulence

(*c*) Intraperitoneally, but this is not very effective (Jungeblut and Hazen, 1930–1 *a*)

(*d*) Intrapleurally (Jungeblut and Hazen, 1930–1 *a*)

(*e*) Application to naso- and oro-pharynx Jungeblut and Hazen (1930–1 *b*) failed to induce resistance by spraying the nose and throat, but others have been more successful (Brodie and Park, 1935 *a*, Kramer, Grossman, and Parker, 1937, 1938, Faber, Silverberg, and Dong, 1943 *a, b*)

(*f*) The intravenous route is not effective Lennette and Hudson (1939) inoculated a number of rhesus monkeys intravenously, and found that practically all succumbed to an intracerebral challenge.

Morgan, Howe, and Bodian (1947) were unable to induce resistance when live monkey virus was given subcutaneously However, they obtained more satisfactory results with large doses of Lansing virus given intramuscularly, antibodies developed, and also resistance to cerebral challenge, the intravenous and subcutaneous routes were not effective.

Bronfenbrenner, 1941). The latter workers titrated antibody by inoculation in mice with Lansing virus as antigen.

Antibodies develop more quickly after injection of live virus by the peripheral routes mentioned in Ch LXXXIV. Antibodies develop after one injection (Rhoads, 1930; Kessel and Stimpert, 1938) Brodie (1934 *b*) found that after a single intracutaneous injection, antibodies appeared after the 6th day, reached their height by the 20th, and lasted for 1 year. However, 2nd injections give a characteristic secondary response, and for the maximum result should be given 10–20 days after the primary stimulus (Brodie, 1934 *b*).

It has been suggested that after subcutaneous injection, certain monkeys and chimpanzees produce antisera potent enough to be used therapeutically (Pettit, Erber, and Kolochine, 1932).

Antibodies develop in monkeys vaccinated with Kolmer's and Brodie's vaccines (see above), phenolized virus, or aluminum-gel virus preparations (Gordon, Hudson, and Harrison, 1939).

In Rodents

Antibodies to the rodent-paralyzing strains develop in cotton rats, mice, and guinea-pigs on recovery from infection. Brown and Francis (1945) found that mice paralyized by an intracerebral injection of the Lansing strain developed neutralizing antibodies 3–6 days after inoculation, whereas the serum of animals becoming paralyzed after 7–9 days had little neutralizing capacity The sera of mice killed 3–6 days after injection, where no paralysis developed, showed as much neutralizing power as those of paralyzed animals killed at the same time.

Antibodies develop in mice vaccinated with ultraviolet irradiated preparations (Milzer, Oppenheimer, and Levinson, 1944, 1945)

In Insusceptible Animals

There is no evidence that the sera of naturally resistant animals neutralize virus (Paraschivesco, 1940, Gordon, 1945 *b*).

Hyperimmune sera can be produced in insusceptible animals.

Horses The fact that only limited quantities of human convalescent serum can ever be available, stimulated attempts to produce antiserum from the horse. Some workers failed to find neutralizing bodies even after repeated injections (e g, Flexner and Lewis, 1910 *e*, Leake, 1918), others were, however, more successful Thus, Neustaedter and Banzhaf (1917) injected a horse with virus-containing filtrates ("digested" with trypsin) and obtained definite virus neutralizing bodies in the serum This work was continued and eventually a highly potent antiserum was produced, neutralizing virus in a dilution of 1 500, whereas human convalescent serum neutralized only in a 1 20 dilution (Weyer, Park, and Banzhaf, 1929, 1931; Rhoads, 1931 *b*; Weyer, 1931–2)

Since that date, numbers of authors have produced immune, even hyperimmune, sera, by injecting horses, often with various purified products (Fairbrother, 1930, Fairbrother and Morgan, 1930, Schultz and Gebhardt, 1930–1 *a*, *c*, 1933–4 *a*, 1934, Schaeffer, 1933–4, Howitt, 1934, Toomey, 1937 *c*, 1938 *b*, 1943 *a*). Such sera may neutralize virus in considerable doses (e g, 1 c c. neutralized 25,000 minimum infecting doses) injected intranasally or intracerebrally. The antibodies are concentrated in the globulin fraction (Toomey, McKhann, and Fahey, 1943).

Pettit's serum A similar serum was produced from the sheep by Pettit (1918), and others have confirmed his original observation (e g, Stewart and Haselbauer, 1928, Howitt *et al*, 1931, Howitt, 1932, 1933, Gordon, Harrison and Hudson, 1934–5, Toomey, 1934–5 *e*, Gordon, Hudson, Harrison, 1939) Pettit also produced a serum from the horse (see Pettit, 1931)

either that Brodie's vaccine is free from active virus, or that it can be used effectively to immunize monkeys

Kolmer's vaccine. McKinley and Larson (1926–7) first showed that sodium ricinoleate might be a useful agent for carrying out immunization of monkeys Kolmer and Rule (1934 *a*, *b*) were able to confirm this observation by finding that subcutaneous and intracutaneous injections of ricinoleated virus conferred slight immunity. The virus was prepared from a 4 per cent. suspension of cord in 1 per cent. sodium ricinoleate, incubated at 37° C. for 24 hours and then refrigerated at 4° to 6° C. for 14 days with occasional shaking. Later, Kolmer and Rule (1936) stated that almost all monkeys injected with 5 doses of ricinoleated vaccine (0 1 to 0 5 c.c per kg.) developed serum antibodies, and the majority was resistant to an intracerebral test injection of active virus

These results were confirmed and amplified when it was stated that for ricinoleated virus to produce effective immunity, sufficient living virus must be present in 0 3 c c. of vaccine to produce paralysis of monkeys on intracerebral injection (Kolmer and Rule, 1937). They further noted that intradermal injection was both safer and more efficient than the subcutaneous route Approximately 1 per cent of monkeys developed paralysis after subcutaneous injection of virus.

Others, repeating Kolmer's work, have failed to immunize monkeys with any regularity, although agreeing with Kolmer that ricinoleated vaccine contains active virus (Olitsky and Cox, 1936, Levaditi, Kling, and Haber, 1936, Kramer and Grossman, 1936).

Virus-serum mixtures Although certain workers have failed to find neutral virus-serum mixtures antigenic (e g., Flexner and Lewis, 1910 *f*), others have found that a more or less effective immunity can be obtained (Romer and Joseph, 1910 *a*, *b*, Rhoads, 1931 *a*, Brodie, 1932 *b*, Kramer and Schaeffer, 1933–4, Kramer, 1936 *b*) It may also be noted that immunity can be produced by simultaneous injection of virus and serum Thus, virus injected intradermally stimulates immunity without producing infection, if it is "covered" by a subcutaneous injection of antiserum given at the same time, or 3 days before or after (Brodie and Goldbloom, 1931, Brodie, 1932 *b*, Flexner, 1932).

Nonspecific injections Monkeys immunized with diphtheria toxoid have been found to survive subsequent injections of poliomyelitis virus (Armstrong and Harrison, 1933), the sera neutralized the virus (Jungeblut, 1934, 1936 *a*)

In Rodents

It has been found that mice can be rendered resistant to the Lansing strain by the intraperitoneal or subcutaneous injection of inactivated formolized virus (Kramer and Geer, 1945)

Levaditi (1942 *e*) found that virus heated to 50° C was inferior to live virus, alumina-gel virus preparations were ineffective.

Perhaps the most hopeful observations yet made in regard to active immunization against poliomyelitis are those of Milzer, Oppenheimer, and Levinson They showed (1944, 1945) that suspensions of mouse brain and cord infected with the Lansing strain were inactivated in under one second by ultraviolet light Mice were vaccinated with 3 injections of 0.5 c c of irradiated suspension at weekly intervals, they showed a marked resistance to a subsequent intracerebral inoculation of living virus Loring *et al* (1947) have rendered cotton rats resistant to cerebral challenge by formalin-inactivated purified virus

SERUM ANTIBODIES IN EXPERIMENTAL POLIOMYELITIS

In Monkeys

Antibodies develop irregularly in monkeys on recovery from infection, and are not detected until the lapse of 2–3 months (Sabin and Olitsky, 1936 *a*, Harford and

some effect was noted (1943). When serum was given after infection, the maximum protection was noted at 6 hours, but some was shown at 96 hours (1943).

MECHANISM OF RESISTANCE TO INFECTION IN EXPERIMENTAL POLIOMYELITIS

It is probable that one mechanism underlying the resistance of immune animals is a definite hindrance to the spread of virus by nerve paths Thus Rasmussen and Clark (1942) found that on inoculation of the sciatic nerve, virus failed to spread to higher levels in immune animals

It appears, however, that when immune monkeys are challenged with virus some invasion frequently occurs, but does not progress far, and clinical evidence of infection is slight or absent. For example, when immune monkeys are infected by nasal instillation, changes occur in the CSF, but virus does not reach the central nervous system (Flexner, 1935 *a*, 1937; Sabin and Olitsky, 1938).

On intracerebral challenge, immune monkeys may develop a febrile reaction within 24–48 hours (Jungeblut, 1931), such animals may show typical lesions of varying extent and intensity, and yet fail to develop clinical signs of infection (Faber, Silverberg, and Dong, 1943 *a*). The same workers (1943 *b*) immunized cynomolgus monkeys by repeated application of virus to the mucosa of the upper respiratory tract and alimentary tract, changes developed in the corresponding peripheral ganglia but not in the CNS. When challenged intracerebrally, changes were found in the cerebrum and brain stem but not in the cord They concluded that these immune animals, as a result of surface exposure, were able to limit the spread of infection, but were not able to prevent the implantation and growth of virus. The immune state was probably associated with the continued presence of virus in the peripheral ganglia.

Further evidence for the theory that a considerable degree of invasion does occur in immune monkeys was afforded by the experiments of Howe and Bodian (see above) They showed that animals recovered from infection contracted by one route could be infected by another route, the second invasion might cause histological changes, but no extension of paralysis Howe and Bodian further emphasized that animals immune to homologous virus may be susceptible to an heterologous strain

The observations just described make it evident that the resistant state in immune animals is at any rate partly dependent on some alteration in susceptible nerve cells

possible adjuvant

but less success-

can influence the

course of infection There are, nevertheless, other observations suggesting that it plays no essential part in the resistant state, its presence may be regarded as an accompaniment, rather than the cause, of the resistant state

Thus, antibodies do not develop in monkeys for several weeks after recovery

is, animals are resistant to challenge (Junge-

n be stimulated by repeated peripheral injection of virus, yet only after numerous injections do the animals become resistant to cerebral challenge (Howitt, 1937 *b*). Resistance to a challenge dose is acquired considerably after the development of antibodies Kessel and Stimpert (1941) found a correlation between the presence of neutralizing antibody and the resistant state in only 50 per cent of monkeys. Lennette and Hudson (1939) came to a similar conclusion

Although serum antibody may well play only a small part in the mechanism of resistance to infection, recent work of Morgan (1947 *b*) on the presence of anti-

ANTIBODIES IN TISSUES IN EXPERIMENTAL POLIOMYELITIS

The relative distribution of antibodies in serum and nervous tissue has been studied by Morgan (1947 *b*). In vaccinated monkeys, no antibodies could be found in the spinal fluid or gray cord at a time when they were present in the serum. In marked distinction was the distribution of antibodies in monkeys paralyzed after cerebral injection, the highest titers of antibodies were found in the anterior horn of the spinal cord, serum and spinal fluid contained little or no antibody. Antibody in the anterior horn appeared between 11 and 16 days after the onset of paralysis, and persisted for at least 4–5 months, by this time antibody was present elsewhere, but in lower titer. The highest titers were found in the anterior horns, then the medulla; lower titers were found in the insusceptible amygdala and visual cortex, and little or no antibody was found in the white matter of the cord or brain.

PASSIVE IMMUNITY IN EXPERIMENTAL POLIOMYELITIS

In Monkeys and Chimpanzees

Human or monkey serum. Numerous authors have recorded the results of injecting human or monkey immune serum in experimental infection, some found that neither prophylactic nor curative injections of such sera have any beneficial effect (e g, Landsteiner and Levaditi, 1910, Abrahamson, 1916–19 *a*, Brodie, 1935 *c*, Gordon, Hudson, and Harrison, 1939, Harrison and Woolpert, 1939). Flexner and Lewis (1910 *e, f*), however, found that intrathecal injections of serum prevented the development of paralysis due to a dose of virus given 18 to 24 hours previously, similar effects were obtained by Flexner and Amoss (1917 *a*). Aycock and Amoss (1923) reported beneficial curative effects when serum was injected intrathecally and hypertonic saline given intravenously, preferably with more antiserum. Schultz and Gebhardt (1935) reported that, at best, a high titered serum might protect against a subsequent small dose of virus.

Monkeys passively immunized by the intravenous route showed no signs of infection following the intravenous administration of virus, starch being given intracerebrally at the same time (Lennette and Hudson, 1939). Lennette and Campbell (1939) found that horse serum regularly penetrated the blood-brain barrier of infected animals in small amount.

Chimpanzees protected by hyperimmune monkey serum became infected when stool was administered orally (Howe and Bodian, 1945 *b*).

Any change exerted by antiserum on the experimental disease is at best slight. No outstanding successes have been obtained which would encourage the use of serum therapy in man.

Horse or sheep serum. Various workers have reported that antipoliomyelitis horse serum has modified the experimentally produced disease, thus, injected intrathecally in the incubation period no paralysis developed (Weyer, Park, and Banzhaf, 1931). Others, however, have found the serum of little use (Rhoads, 1931 *b*, Howitt, 1934).

Pettit's serum has been said to show some prophylactic powers in monkeys against subsequent injections of virus (Howitt *et al*, 1931, Howitt, 1932). It is probably, however, of doubtful value clinically (Marinesco, Manicatide, and Draganesco, 1929, Howitt *et al*, 1931, Violle and Montus, 1935).

In Rodents

Kramer worked with the Lansing strain in mice and found that a significant proportion of 3-week-old animals was protected against an intracerebral injection, by the intraperitoneal administration of 0.03–5 c c of human convalescent serum (1941). This protective action of serum lasted for 72 hours, and even after 2 weeks

CHAPTER LXXXVIII

IMMUNITY IN HUMAN POLIOMYELITIS

ALLERGY

ALTHOUGH Jungeblut (1930–1 *c*) showed that convalescents reacted to the intradermal injection of heated virus filtrates with a definite erythema, others have been unable to detect any difference between convalescents and controls (Harmon, Harrison, and Kernwein, 1932–3, Sabin, Park, and Jungeblut, 1933).

ACTIVE IMMUNITY FOLLOWING INFECTION

A clear distinction should be drawn between what is implied by the terms "relapse" and "second attack" in poliomyelitis Relapses are most uncommon and occur within 3 months of the first attack It is possible that the virus is carried in the respiratory tract during the interval, as relapses have occurred after rhinopharyngitis and pertussis (Loeschke, 1934).

Second attacks occur from 2 to 16 years after the first, but are generally thought to be rare (e g, Francis and Moncrieff, 1919, Still, 1930, Moore, 1934, Quigley, 1934, Cohen, 1935, Fischer and Stillerman, 1938; Toomey, 1938 *c*; Nelson and Green, 1943; Wyllie, 1945, Lipscomb, 1947).

However, from their observations in Buffalo, Bridge, Clarke, and Abbe (1946) cast doubt on the existence of significant acquired immunity The whole question is in need of further study. Fundamental is the question whether or not there are several antigenic types of virus

It is certain that in countries where the disease is endemic, the majority of persons becomes immune to infection at a fairly early age. Some of these persons may have suffered from mild symptoms, but the majority has acquired resistance through being healthy carriers The intestine is probably a more important site of carriage than the nasopharynx. It is possible that enough virus is absorbed to stimulate the production of antibodies and cell resistance. It is possible, however, that the "immunizing" agent may actually act locally in the epithelial cells of the gastrointestinal tract by blockading them against later invasion (see Evans and Green, 1947)

ACTIVE IMMUNITY FOLLOWING VACCINATION

Two vaccines have been very widely used in America in an effort actively to immunize children against poliomyelitis, namely, Brodie's formolized and Kolmer's ricinoleated vaccines. A considerable amount of experimental work was carried out with these vaccines before they were used in human experiments (see p 1009)

Brodie's vaccine Brodie (1934–5 *a*) injected 12 children both intracutaneously and subcutaneously The inoculum consisted of 5 c c of a 10 per cent. virus suspension inactivated with 0 1 per cent formalin for 16 to 48 hours, 1 to 2 5 c.c. was injected intradermally and the remainder subcutaneously, no general or local disturbance was noted. After vaccination the children's sera showed an appreciable increase in the antibody titer. Brodie (1935 *a*) found that 0 05 per cent formalin was as effective

Later, Brodie and Park (1935 *b*) reported the results of over 2,300 vaccinations with formalized virus, in which only 17 children showed local reactions, and no serious accident occurred A rise in the neutralizing antibody titer of the serum was noted beginning after 1 week, reaching its height in 3 to 4 weeks

Kramer (1936 *a*) vaccinated a small group of children with Brodie's vaccine. Some 2 months later 50 per cent had developed neutralizing antibodies, but of a *parallel* uninoculated control series 41 per cent. had also developed antibodies Aycock and Hudson

body in the anterior horn a few days after the onset of paralysis, throws new light on the subject (see p. 1012). She suggests that this local antibody may prevent further infection, if the challenge is given by the same route. This may correlate with the observations of Howe and Bodian (above) that previously uninvaded paths in resistant monkeys may become infected with virus when the animals are inoculated by routes different from the original. It may be that this is possible because of a relative absence of antibody.

OCCURRENCE OF SERUM ANTIBODIES

Normal Persons

The term "normal" in connection with poliomyelitis signifies persons who have never suffered from any recognizable manifestation of infection, nor have been in close contact with a case, so far as they are aware. It is well nigh impossible, however, to be certain that so-called normal persons have never suffered from abortive (nonparalytic) poliomyelitis or been carriers Numerous [illegible] orded the presence of virus neutralizing [illegible] rmal persons (e [illegible] 1929–30, Aycock [illegible] Gebhardt, 1930–1 [illegible], Netter, Levaditi, and Hornus, [illegible] 1935 a, Paul and Trask, 1935, Brodie, Fischer, and Stillerm[illegible], 1937, Howitt, 1937 b).

The sera of many normal adults neutralize several strains of virus (Aycock, 1942 c)

Age distribution of immune bodies Young infants receive passive immunity from their mothers, and tests carried out on maternal sera and cord bloods show a complete correspondence between the presence of antibodies in mother and child, approximately 80 per cent. of mothers' and babies' sera neutralize the virus (Aycock and Kramer, 1930 *a*, *c*).

The results of various examinations of neutralizing antibody in children's sera at different ages have been compiled of children aged 0 to 4 years, 37 per cent. show the presence of immune bodies, from 10 to 14 years the sera give 58 per cent. of positive readings, while over 15 years 73 per cent. of sera neutralize the virus (Harmon and Harkins, 1936). More recently, antibody tests have been carried out in mice, and have confirmed the earlier observations that the bulk of adult sera neutralizes the virus, and that the percentage of sera neutralizing increases with age (Haas and Armstrong, 1940, Armstrong and Davis, 1945; Turner, Young, and Maxwell, 1945, Brown and Francis, 1947 *b*) There is thus a steady increase in the percentage of sera neutralizing the virus with advancing age.

Geographical distribution of immune bodies The various authors already mentioned examined sera from parts of the world (especially the United States) where poliomyelitis is common. Sera have also been examined from parts of the world where epidemic poliomyelitis is less common. Thus, the sera of 18 19 Liberian (African) males over 15 years of age neutralized the virus (Hudson and Lennette, 1933) The sera of 3 adult Eskimos and 11 Chinese all showed positive neutralizing power (Jungeblut, 1933), as did another series of 8 10 Chinese sera from Peiping (Lennette and Hudson, 1932–3) The sera of 8 adults from Porto Rico also neutralized the virus (Soule and McKinley, 1931–2). The sera of 9 10 Filipinos over 12 years of age neutralized the virus (Doull, Hudson, and Hahn, 1935) Hudson and Lennette (1938) reported another such series of tests. They found that the majority of sera of persons from Thursday Island (Australia), Formosa, and Brazil neutralized the virus As poliomyelitis only occurs sporadically in these areas, they suggested that this result was evidence for the wide distribution of poliomyelitis virus

More recently, similar results have been obtained using strains such as the Lansing as antigen, in neutralization tests in mice. Thus antibodies have been found very commonly in the sera of "normal" West Africans (Findlay, Anderson, and Haggie, 1946, Olitsky and Findlay, 1946)

It is evident therefore that the serum of "normal" adults in most parts of the world neutralizes the virus The antibody in normal sera cannot be distinguished in its properties from that in convalescent sera (see, e g, Harrison and Hudson, 1940)

(1936) recorded a similar rise in titer in vaccinated persons' sera, but no more than occurred in a control uninoculated group.

A field trial of this vaccine was made by Gilliam and Onstott (1936) during a poliomyelitis outbreak in North Carolina and Virginia, 458 persons were inoculated with vaccine and 676 controls were used However, not a single case of poliomyelitis developed in the controls, so no opportunity was presented to test the efficacy of the vaccination

With regard to the safety of Brodie's vaccine, Brodie and Park (1935 *b*) found that 5 c c of virus inactivated by 0 1 per cent formaldehyde for 8 to 12 hours was noninfective for monkeys It should be remembered, however, that Trask and Paul (1936) found that 0 1 per cent. formalin did not destroy the virus in 24 hours in the refrigerator

Although no cases of poliomyelitis appear definitely to have been attributed to the use of Brodie's vaccine, some hesitancy should be shown in regarding it as avirulent

Kolmer's vaccine With regard to any type of vaccination, it may justifiably be asked whether it is worth while, as so very few children actually contract the infection, compared to the number at risk Kolmer (1935 *b*) has given his justifications for embarking on a scheme of vaccination (1) The active immunity induced by the natural disease is so efficient that it was hoped vaccination might accomplish the same effect (2) Although the attack rate is low the disease seems to be on the increase (3) The sera of approximately 80 per cent of children under 4 years of age do not contain any appreciable quantity of antibody (4) Although only 25 per cent. of children over 15 fail to show virus neutralizing bodies, this process of active immunization should not be regarded as adequate protection (5) Monkeys could be immunized with ricinoleated virus (6) Ricinoleated vaccine stimulated the production of antibodies in man, which appeared even after 4 days, and no person receiving 3 doses contracted poliomyelitis, although some persons receiving 1 to 2 doses did

Kolmer's vaccine differs from Brodie's in that it is definitely known to contain active virus Kolmer and Rule (1937), working with monkeys, found they could not produce active immunity unless there was enough virus in 0 3 c c of vaccine to produce paralysis on intracerebral injection Kolmer has attached some importance to the fact of the virus being monkey passage strain and, therefore, in his opinion, of lowered virulence for man As events have shown, the virus retained sufficient virulence to infect some of those vaccinated, even by the subcutaneous route

A preliminary batch of 25 children was injected subcutaneously with a 4 per cent cord suspension in 1 per cent. sodium ricinoleate (Kolmer and Rule, 1934 *a*, *b*, Kolmer, Klugh, and Rule, 1935 *a*, *b*; Kolmer, 1935 *a*). The vaccine was prepared by emulsifying 8 gm. of monkey cord in 100 c.c. of sterile saline, after fine mesh filtration, equal parts of 2 per cent. sodium ricinoleate in saline were added (giving a final strength of 4 per cent cord in 1 per cent ricinoleate) The mixture was incubated at 37° C for 24 hours, and thereafter kept in the refrigerator at 4° to 6° C for 14 days, being shaken occasionally. In certain cases phenylmercuric nitrate or mercurophen was added (Kolmer, 1936 *b*) Three injections were given at intervals of 7 to 10 days No serious disturbance was noted although there might be some local tenderness at the site of inoculation

Antibodies appeared, even as early as after 4 days, in those who failed to show them before the treatment, in other cases the preexisting titer was increased Repeating this work, Aycock and Hudson (1936) showed that antibodies appeared after vaccination, but not in any higher percentage than occurred in a control unvaccinated group

Encouraged by this preliminary success, Kolmer and Rule (see 1937) sponsored the inoculation of some 10,725 individuals in 36 different States between April and September 1935 Injections were given subcutaneously and no case receiving 3 full doses contracted poliomyelitis Unfortunately, however, 10 cases of poliomyelitis followed in those receiving fewer doses Further issue was refused (Kolmer, 1936 *a*)

Leake (1935, see also 1936 *b*) recorded some 12 cases of paralysis following injection with 2 unnamed vaccines, presumably at least 10 of these cases arose following Kolmer's vaccine The level of the spinal cord first affected usually corresponded to the injected extremity, suggesting a direct neural spread of the virus At the time of writing, Leake recorded that 6 of these cases had died

It is unlikely that active immunization with attenuated virus will be applied to children again (see Kolmer, 1938), although suggestions have been made that a possible line of approach to the problem is oral immunization with a so-called nonparalyzing strain

tion by a single strain, and found that the majority of convalescent sera gave a specific response with this strain

Convalescents from Abortive Attacks

A number of workers has shown that abortive attacks of poliomyelitis give rise to the production of antibodies in convalescence (see, e g, Netter and Levaditi, 1910 *b*, Anderson and Frost, 1911, Howitt, 1932, Eagles, Jensen, and Henningsen, 1937, Gildemeister, 1939).

Virus Neutralizing Properties of Body Fluids

Policidal properties have been found in the normal nasopharyngeal secretion (*Amoss and Taylor, 1917*), *the nasal secretion* (Howitt, 1937 *b*), the tears (Jungeblut, 1934–5) This poliocidal substance is probably of a lysozym nature. The cerebrospinal fluid of convalescents neutralizes the virus, even after 18 months (Meyer and Le Guyon, 1932, Meyer, 1934), probably due to a true virucidal antibody.

SIGNIFICANCE OF THE WIDESPREAD DISTRIBUTION OF ANTIBODY

About 75 per cent of supposedly normal persons' sera neutralize poliomyelitis virus This can most readily be explained on the basis of widespread subclinical infection However, *two alternative theories have been advanced*

The Theory of Infection

This theory is orthodox, and affirms that the presence of virus neutralizing antibody is due to previous contact with poliomyelitis virus It is now known that poliomyelitis virus enjoys a widespread distribution It is thought to occur in practically every country, and to infect a very much larger number of persons than actually suffers from clinical evidence of infection The majority of persons is thought to become infected in childhood, probably through close contact with a *case, paralytic or abortive Such persons probably harbor the virus in the naso*pharynx for a few days, and in the intestines for a few weeks This relatively short period of carriage is sufficient to give rise to active immunity characterized by the development of resistance to infection and of serum antibodies This view, confirmed by recent work on the epidemiology of the disease (Ch LXXXIII was supported on statistical grounds by Stocks (1932) He believed that in endemic areas, for every 1 person showing paralysis, over 100 acquired resistance by latent epidemization.

The Theory of Physiological Maturation

Jungeblut has been largely responsible for criticizing the infection theory, and propounding an alternative (Jungeblut, 1934, 1935–6, 1936 *b*, 1937 *a*, *b*, Jungeblut and Engle, 1931–2, 1932 *a*, *b*, 1933, Jungeblut, Meyer, and Engle, 1934, Jungeblut

1 Even on its original appearance in a country, the disease has always selectively attacked the prepubertal child (contrast, e g, measles epidemics in virgin soil) If immunity is dependent upon subclinical infection, then all ages should be susceptible, as adults have had no opportunity for previous contact with the virus.

CONTACTS

It has been stated that the sera of those with a history of frequent exposure to infection have a higher immune body content than those without such obvious contact (Brodie, 1932 *c*; Brodie and Park, 1935 *a*). Kramer (1932) examined a group of persons who were in intimate and prolonged contact with a case of poliomyelitis At the beginning of the experiment, these persons showed no immune bodies, whereas after 6 months they had developed them, although they never showed any signs of abortive attacks of the disease. A control group of persons who came into less intimate contact did not develop immune bodies. However in the 1937–8 Victoria epidemic Burnet and Jackson (1939) did not find that contacts developed antibodies.

CONVALESCENTS FROM PARALYTIC ATTACKS

The development of immune bodies during convalescence from frank paralytic attack has been noted by many (e g, Netter and Levaditi, 1910 *a*, Trask and Paul, 1933, Brodie, 1934 *c*, Harmon *et al.*, 1936, Brodie, Fischer, and Stillerman, 1937). Estimates of the time of first appearance of these bodies vary from the 3rd day after onset of paralysis (Kling and Levaditi, 1913 *b*) to the 9th to 14th day (Harmon *et al.*, 1936).

In general, samples of convalescent sera are more strongly virucidal than normal sera (see Aycock, Luther, and Kramer, 1929; Southby and McKie, 1933; Brodie, 1934 *c*, Kessel, Stimpert, and Fisk, 1939). However, certain normal samples may show a titer which is quite as high as, if not higher than, this It has been stated that 0.04 c.c. of a strongly virucidal convalescent serum should neutralize 80 m.c p. doses of virus (Brodie, 1934 *c*)

Until fairly recently, it was assumed that the majority of convalescent sera showed the presence of virus neutralizing properties, but Harmon and Harkins (1936) compiled the results of a number of such examinations, and disclosed that of 183 convalescent sera tested, 39 8 per cent gave a negative result. Later observations have served to confirm this view (Gildemeister, 1939, Burnet *et al*, 1939, Burnet and Jackson, 1939, Burnet, 1940, Turner and Young, 1943) Thus, Burnet and his colleagues investigating a number of cases in the 1937–8 Victoria epidemic found no rise in titer when acute phase samples were compared with convalescent samples obtained 2–3 months later, they used both the MV and a local strain as antigen. Turner and Young (1943) used the Lansing strain as antigen and carried out the titrations in mice They found that in 52/64 cases, the acute and convalescent phase samples gave the same results. They found only one patient who showed a complete antibody response in convalescence Brown and Francis (1947 *b*) using the Lansing strain, only detected a rise in antibody titer in 3/74 convalescents

Burnet, Turner, and Young, and Brown and Francis drew attention to the fact that many of their patients had neutralizing antibody in their blood at the onset of the disease. Hammon and Izumi (1942 *a*) found that about 50 per cent of sera in the acute phase neutralized the Lansing strain. The question of the virus used as antigen in these tests is of primary importance, in view of the antigenic differences known to exist between virus strains Burnet used a local strain, so his results definitely point to a failure of development of antibody However, Turner and Young,

egative results were due to

causing the epidemic The

used depends on the anti-

ot sufficiently well known

as yet. Aycock (1942 *c*) has pointed out that apparent discrepancies in the neutralization test may be explicable by the fact that different strains may be present in a single epidemic. He studied an outbreak where the epidemiology pointed to infec-

they caused immature monkeys to menstruate by injecting them with anterior pituitary extract, but no immune bodies developed

Physique. Jungeblut draws attention to the descriptions given by Draper (1932, 1935) of the typical poliomyelitis child (see p. 919), all indicating some widespread endocrine disturbance. However, these stigmata are not accepted as specific by Levine, Neal, and Park (1933).

Ablation of endocrine glands The sera of Nicaraguan cebus monkeys were found to ne [illegible] -2), after adrenalectomy, however, they [illegible] ortical hormone the neutralizing power [illegible] and Steinbach (1934–5) also found that [illegible] of natural poliomyelitis antibody. The antibody present in animals recovered from infection was not so affected by adrenalectomy. Removal of thyroid or testicle, or the injection of thyroxin had no effect on the refractory state of monkeys recovered from infection (Levaditi and Haber, 1935).

Aycock (1936, 1937) castrated immature female rhesus monkeys and treated them with estrin Although the numbers were small, it appeared as if the estrin-treated animals were more resistant to nasal inoculations of virus than castrates who had received no estrin, or normal controls (see also Curley and Aycock, 1946).

The effect of vitamins It was found that if monkeys injected with virus intracerebrally were treated with repeated doses of vitamin C (5 mg) 50 per cent. survived If the dose of vitamin was considerably increased, the results were not so good, the majority of animals succumbing (Jungeblut, 1937 *a*) Later, Jungeblut (1937 *b*) reported that 32 per cent. of monkeys injected intracerebrally survived without paralysis when treated with natural vitamin C. Treated with synthetic vitamin only 10 8 per cent survived (see also Jungeblut, 1939). Sabin (1939) reported, however, that vitamin C had no effect on the course of infection after intranasal instillation of virus Continuing these researches, Jungeblut and Feiner (1937) investigated the vitamin C content of the tissues of monkeys infected with poliomyelitis They found the content slightly below the average in the adrenals and nervous tissue of paralyzed monkeys (treated or not with vitamin), the content of the organs of treated, nonparalyzed monkeys was markedly higher. Kasahara and Gammo (1938), however, found no change in the vitamin C content of the cerebrospinal fluid in experimental poliomyelitis

Autarceologic susceptibility This term has been used by Aycock (1929, 1930, 1941) While not de [illegible] the virus, Aycock h[illegible] logic susceptibility " [illegible] the normal physiological functions of the body. He attaches great importance to seasonal variations giving rise to physiological imbalance and resulting susceptibility to infection. Aycock thus supports Jungeblut in his claims that physiological mechanisms are responsible for resistance to poliomyelitis Aycock's (1936, 1937) work with castrated monkeys has already been mentioned He holds that susceptibility to poliomyelitis may depend on some pituitary gonad imbalance.

Conclusions Jungeblut (1937 *a*) has formulated the following expression of his views Poliomyelitis is essentially a developmental error of youth in which protection is due to physiological factors. Man is normally insusceptible and can carry the virus with impunity, the disease only occurring in a few, and this due to some transient physiological abnormality

The Theory of Nonspecific Infection

It has been suggested that the presence of poliomyelitis antibody is due to infection with antigens chemically sufficiently close to the virus to provoke an antibody response similar to that provoked by the virus itself. There is little or no evidence in favor of this theory with one exception some relative data have been

2. Neither paralytic nor abortive cases are common enough to explain the widespread distribution of immune bodies

3. Poliomyelitis can occur in persons who have been exposed to infection for such a length of time that resistance might reasonably be expected to have developed

4. In the United States the same towns are frequently revisited by epidemics in later years, but the inhabitants do not appear to have become immunized.

5 Jungeblut states that there is no evidence that a subinfective dose of virus can provoke immunity, citing his own experiments in which no immunity followed repeated spraying of a monkey's nasopharynx (Jungeblut and Hazen, 1930–1 *b*)

6 It has been mentioned already that the sera of Filipinos, Porto Ricans, Liberians, Eskimos, and Chinese neutralize the virus As poliomyelitis is rare in the lands inhabited by these people, it is argued that the immune body may have been produced in the absence of the specific virus

7 It may be mentioned here that neutralizing antibody has been found in the sera of normal pregnant mares (Jungeblut, Meyer, and Engle, 1934, Jungeblut, 1935–6). Normal cebus and rhesus monkeys' sera also neutralized the virus (Jungeblut and Engle, 1931–2)

Jungeblut and his colleagues believe that immunity to poliomyelitis is dependent on investigated a number of possibilities

One of the earliest reports on the blood gro hat of *Grooten and Kossovitch (1930)*, who noted that a higher percentage of poliomyelitis patients belonged to group A than did controls, slightly fewer poliomyelitis patients belonged to group B and O than would be expected, and none at all to AB

Jungeblut and Smith (1932) made a more extensive investigation They noted that below 5 years of age the incidence of blood groups in paralytic cases was perfectly normal. With advancing age, however, there was a diminution in those belonging to B and a slight increase in O After 5 years of age most deaths occurred in groups other than B, particularly A (5 to 10 years) or O (over 10 years)

With regard to blood donors, they noted that the sera of 33 per cent of A, 50 per cent of O and AB, but 80 per cent. of B groups neutralized the virus These figures were confirmed by Jungeblut (1933), who examined the sera of New Yorkers who had lived there through the 1931 epidemic, he made the additional observation that when these sera were titrated, O neutralized virus diluted 1 20, A, 1 5, but B neutralized virus diluted even 1 60

The subject attracted some interest and a number of other papers has appeared 1933, Cowie, Parsons, and Lowenberg, 1934–5, vhether any significance can be attached to the question of the varying incidence of poliomyelitis in different blood groups following the work of Madsen, Engle, Jensen, and Freuchen (1936). These workers investigated the blood groups of approximately 1,200 patients and 20,000 normals *during the 1934 Danish epidemic They concluded that there was no significant* difference in the incidence of cases occurring in each group, when contrasted with controls More recently, Erb *et al* (1938) studied the blood groups *in 703 cases* during the 1937 autumn epidemic in Toronto, they found that susceptibility to infection bore no relation to blood grouping. With regard to the greater virus neutralizing power claimed for group B sera, further observations are required, if possible on a large scale

Menstruation The immune body content of the sera of two women varied, on one occasion giving a positive neutralization test, and on another a negative (Jungeblut and Engle, 1933), indicating that physiological mechanisms may affect titer

Similarly, it was found that the sera of 2 monkeys examined before the onset of the menstrual cycle failed to neutralize, reexamined 10 days after the onset of bleeding, a positive result was obtained (Jungeblut and Engle, 1931–2) A more extensive study was carried out by Hudson, Lennette, and King (1934) who found that sera taken at various stages of the menstrual cycle failed to neutralize Further,

they caused immature monkeys to menstruate by injecting them with anterior pituitary extract, but no immune bodies developed.

Physique. Jungeblut draws attention to the descriptions given by Draper (1932, 1935) of the typical poliomyelitis child (see p. 919), all indicating some widespread endocrine disturbance. However, these stigmata are not accepted as specific by Levine, Neal, and Park (1933)

Ablation of endocrine glands. The sera of Nicaraguan cebus monkeys were found t ... after adrenalectomy, however, th ... hormone the neutralizing po ... Removal of thyroid or testicle, or the injection of thyroxin had no effect on the refractory state of monkeys recovered from infection (Levaditi and Haber, 1935).

Aycock (1936, 1937) castrated immature female rhesus monkeys and treated them with estrin. Although the numbers were small, it appeared as if the estrin-treated animals were more resistant to nasal inoculations of virus than castrates who had received no estrin, or normal controls (see also Curley and Aycock, 1946).

The effect of vitamins It was found that if monkeys injected with virus intracerebrally were treated with repeated doses of vitamin C (5 mg.) 50 per cent. survived. If the dose of vitamin was considerably increased, the results were not so good, the majority of animals succumbing (Jungeblut, 1937 *a*). Later, Jungeblut (1937 *b*) reported that 32 per cent. of monkeys injected intracerebrally survived without paralysis when treated with natural vitamin C. Treated with synthetic vitamin only 10 8 per cent. survived (see also Jungeblut, 1939). Sabin (1939) reported, however, that vitamin C had no effect on the course of infection after intranasal instillation of virus. Continuing these researches, Jungeblut and Feiner (1937) investigated the vitamin C content of the tissues of monkeys infected with poliomyelitis They found the content slightly below the average in the adrenals and nervous tissue of paralyzed monkeys (treated or not with vitamin); the content of the organs of treated, nonparalyzed monkeys was markedly higher Kasahara and Gammo (1938), however, found no change in the vitamin C content of the cerebrospinal fluid in experimental poliomyelitis

Autarceologic susceptibility This term has been used by Aycock (1929, 1930, 1941) While not denying the importance ... the virus, Aycock has stressed the rôle of ... logic susceptibility " Autarcesis is the powe ... the normal physiological functions of the body. He attaches great importance to seasonal variations giving rise to physiological imbalance and resulting susceptibility to infection Aycock thus supports Jungeblut in his claims that physiological mechanisms are responsible for resistance to poliomyelitis. Aycock's (1936, 1937) work with castrated monkeys has already been mentioned He holds that susceptibility to poliomyelitis may depend on some pituitary gonad imbalance.

Conclusions Jungeblut (1937 *a*) has formulated the following expression of his views Poliomyelitis is essentially a developmental error of youth in which protection is due to physiological factors Man is normally insusceptible and can carry the virus with impunity, the disease only occurring in a few, and this due to some transient physiological abnormality.

The Theory of Nonspecific Infection

It has been suggested that the presence of poliomyelitis antibody is due to infection with antigens chemically sufficiently close to the virus to provoke an antibody response similar to that provoked by the virus itself. There is little or no evidence in favor of this theory with one exception. some relative data have been

obtained in the case of diphtheria. Thus monkeys immunized against diphtheria may resist infection with poliomyelitis virus (Armstrong and Harrison, 1933) Their sera may neutralize the virus *in vitro* (Jungeblut, 1934, 1936*a*). Zingher (1917*a*) found that 80 per cent. of children convalescent from poliomyelitis gave a positive Schick test, as against 30 per cent. of normal children; Dwyer (1938) found that Australian children immunized against diphtheria were less likely to contract poliomyelitis than unimmunized children. Brodie and Park (*1935 a*), however, using the Schick test, could find no relationship between immunity to diphtheria and poliomyelitis.

This theory has received support from Burnet (Burnet and Jackson, 1939, Burnet *et al.*, 1939). He concluded that poliomyelitis antibody is not the result of *exposure to, or infection with, the virus of poliomyelitis.* It is produced in response to another or [illegible] opounded by Burnet is that the an [illegible] ociated with increasing age, and [illegible] correlation between the presence [illegible] n in young children from industrial districts, and suggested they were both acquired at the same age and in the same environmental circumstances.

Conclusions

We do not feel that a sufficient case has been made out against the orthodox view that antibody results from exposure to the virus, as is accepted without question in other virus diseases. The work of the last few years has made it increasingly evident that poliomyelitis virus is, in fact, a widespread infecting agent in man

Thus, the principal difficulty of earlier workers in accepting the infection theory *seems largely to have disappeared. Further observations are required on the antibody* response of close contacts who develop infection and excrete virus

IMMUNE SERUM THERAPY IN HUMAN POLIOMYELITIS

One of the most practical points to discuss in this chapter is the question of the administration of immune serum in the prevention and treatment of poliomyelitis, and as an introduction it is as well to consider [illegible] the use of serum is based on the assumption that [illegible] fect on the virus *in vivo* However, immune s[illegible] effect on the experimental disease (*see above*). *Further, it has already been mentioned* that it is now doubtful whether the antibody has any essential significance in resistance to infection.

In the second place, when serum therapy was introduced over 30 years ago by Netter, Gendron, and Touraine (1911), it was generally held that poliomyelitis showed 2 distinct stages of infection. At first the virus was thought to circulate in the blood, and only later did it localize in the meninges According to this view, the use of serum was quite rational, as there was some likelihood of virus in the blood being neutralized Even later, the injection of serum into the spinal theca might be hoped to neutralize virus in the meninges and prevent the development of paralysis.

As mentioned on many occasions in these chapters, current views on the pathogenesis of poliomyelitis differ widely from those in vogue 20 to 30 years ago Thus, it is now believed that virus is present in the central nervous system from the beginning, and that no stage of primary blood involvement occurs Now, if the virus is present in the axons it is unlikely that serum will be able to influence *it at all* readily At the outset, therefore, it appears that there is little justification for expecting serum therapy to be of much avail, for even if the antibody has any action *in vivo*, it is difficult for it to reach the virus The examination of carefully controlled series of administrations of serum supports the modern view, as it is gen-

erally agreed that such observations have failed to detect any benefit in serum-treated cases.

Animal Serum

Pettit (1935) has advocated the use of animal sera, and claims that, if given in the preparalytic stage, paralysis is prevented If given later, paralysis may be cured, or spread prevented (see also Casassa, 1938). The bulk of opinion is, however, against the use of heterologous sera, and these results must be accepted with some reserve.

The Choice of Human Serum

Three different types of donor are commonly used to supply poliomyelitis immune serum: convalescents from paralytic attacks, convalescents from abortive attacks, and normal individuals.

Donors convalescent from paralytic attacks. This source of supply is probably

Brodie, 1934 c)

Donors convalescent from abortive attacks The sera of these convalescents may show as high a percentage of antibodies as those convalescent from paralytic attacks, and so may be used in therapy (Anderson and Frost, 1911, Howitt, 1932, Eagles, Jensen, and Henningsen, 1937, Heck, 1942)

Normal sera Normal sera may show virus neutralizing bodies in high concentration, and it has been recommended that ordinary blood transfusion donors be used, and that their serum be tested for immune body as well as for blood grouping (Faber, 1931)

Pooled sera. When large quantities of immune serum have to be available, it is obviously simplest to pool all the supplies As the immune body content of different samples is somewhat variable, the titer of pooled sera is usually low Strictly speaking, all sera to be used in therapy should be subjected to a virucidal test before being pooled, and those of low titer discarded (see, e g, Faber, 1931) To minimize the risk of serum jaundice, pools should not consist of more than 10 samples

International standard serum Madsen and Jensen (1936) have prepared a standard antiserum which is available for use throughout the world After the cessation of the 1934 Danish outbreak, some 300 liters of serum which remained were desiccated and the dry powder carefully mixed, 500 gm of dry powder were dissolved in 5 liters of distilled water This was then centrifuged at 10,000 r p m for 1 hour, filtered through a Seitz, tested for sterility and distributed in 5 c c amounts in nitrogen-filled ampules

The use of whole blood in poliomyelitis Intramuscular injections of 60 c.c. of parents' whole blood were recommended by Stokes *et al* (1935). Later it was reported that unpleasant reactions might occur if the cells were incompatible (Rapoport and Stokes, 1937)

Gamma globulin Bahlke and Perkins (1945) gave 20 c c intramuscularly to those under 1 year, and up to 100 c c in the case of those of 12 and over There was no benefit

Route of inoculation The serum is most commonly given intrathecally with or without an accompanying intravenous injection Intrathecal injection provokes a polynucleosis in the spinal fluid, and this may itself *prove beneficial* (Sophian, 1916, Zingher, 1917 *b*) The accompanying meningeal irritation, however, increases the neck stiffness and Kernig's sign (Aycock, Luther, and Kramer, 1929). It may also be administered subcutaneously or intramuscularly

Time of inoculation Although some of the earlier workers (e g, Netter, 1915) claimed that the serum benefited paralyzed cases, for some time now its use has

been more or less restricted to the preparalytic stage in the hope of aborting the onset of paralysis.

Dose. In the earlier days about 10 c.c. used to be given on several occasions More recently workers have used doses of 20 c.c or more intrathecally, combined with 50 c.c. intravenously, up to 50 c c. can be given intramuscularly.

A valuable adjunct is to inject hypertonic saline intravenously as well as the serum, thus tending to lower intracranial tension and lessen edema and pressure (Aycock and Amoss, 1923).

Preservation and storage. The serum may be heated to 55° C. for half an hour, or treated with 0 2 per cent. tricresol (Amoss and Chesney, 1917) or 0.2 per cent. phenol (Brodie, 1934 *c*), but a better method would appear to be that of Morgan

Morgan's method. This method has been used in Australia (Morgan, 1927, 1928, Burnet and Macnamara, 1929, Macnamara, 1929, Macnamara and Morgan, 1932)
Blood is withdrawn into oxalate and after c [illegible]
calcium chloride is added to cause clotting [illegible]
filter (EK), and after a second filtration, [illegible]
into ampules This product is free from ar [illegible]
children

Another convenient method of storage would be to desiccate, as used by Madsen and Jensen (1936). After one year's storage of serum preserved with 0 2 per cent. phenol, only 20 per cent of the neutralizing power was lost (Brodie, 1934 *c*) After 2 years' storage, 50 per cent had been lost, and finally after 4 years', only 25 per cent. of the original neutralizing power remained. Burnet and Macnamara (1929) reported that serum sealed in ampules without antiseptic could be stored for 3 years without significant loss of properties

Results: (a) relatively uncontrolled.

Numerous authors from all parts of the world have used immune serum, and it must be admitted that many have expressed satisfaction, they have reported the prevention of paralysis, falls of temperature, and clinical improvement dating from the inoculation Poliomyelitis is a capricious disease and unfortunately very few of the authors to be mentioned have carried out adequate controls (Netter, Gendron, and Touraine, 1911; Netter, 1915; Amoss and Chesney, 1917, Fischer, 1917, Shaw, Thelander, and Fleischner, 1925; Aycock, Luther, and Kramer, 1929, Marinesco, Manicatide, and Draganesco, 1929, Macnamara, 1929, Faber, 1931, Levinson, McDougall, and Thalhimer, 1932, Macnamara and Morgan, 1932, Petter, 1933, Pohlen, 1934, 1936 *a*, Jensen, 1934–5, Hegler, 1936, Jackson, 1937, Kauders, 1937 *b*, Cadham, 1942)

Harmon (1934) has published a lengthy article which should be read by all interested in this subject He analyzes the published reports of some 4,400 treated and 2,660 untreated cases He stresses the failure of statistical presentation to demonstrate the value of serum, and finds that the outcome in treated preparalytic cases does not differ from the average for untreated patients He allows, however, from clinical observations that the serum may have some value

(b) Controlled.

The great majority of published reports has not been free from the criticism that there were insufficient controls, and in fact in many series there were none at all Numerous authors have expressed dissatisfaction with the use of serum, but again these results were often not well controlled, and carried little weight The most important controlled observation on the value of serum, given in the preparalytic stage, was carried out in New York in the 1931 epidemic by the Health Department and the Academy of Medicine, the results were reported by Park (1932) and Fischer (1934) Thus, Fischer reported on 447 treated and 102 control patients

The outcome for the treated persons was considered to be no better, if as good, as for the controls This report, in association with recent experimental work, will doubtless considerably modify current practice in many parts of the world where serum is at the moment used freely. Of recent years, several other unfavorable reports have appeared. For instance, during the 1936–7 Memphis (Tenn.) outbreak, serum was administered to preparalytic and paralytic cases, and a control group was left untreated (Levy, 1938). *Although the total numbers were not large, it was* perfectly definite that serum exerted no beneficial effect. Serum was administered to test, and withheld from control, groups in the 1937 Ontario epidemic (Hyland *et al.*, 1938). The incidence of paralysis and death was essentially similar in the two groups; Silverthorne, Hawke, and Brown (1941) came to a similar conclusion. Mai (1938) carried out an adequately controlled series of administrations in Bavaria and found no evidence that serum had any value. Athenstaedt (1938), from a review of over 3,000 treated and 555 untreated cases, concluded that serum was of no value Bahlke and Perkins (1945) found gamma globulin to be of no value.

World use of serum Serum has been used on a large scale mainly in the United States, Scandinavia, Germany, and Australia, but is now much less popular

In the 1933–4 Danish epidemic some thousands of cases were treated On clinical [illegible] vas [illegible] acy [illegible] of [illegible] *6 a;* [illegible] ate [illegible] as [illegible]

In conclusion, therefore, the accumulated evidence is against the value of immune serum therapy, and in a review of the subject Faber (1941) concluded that there was little to support the belief that it could be curative.

MECHANISM OF RESISTANCE IN HUMAN POLIOMYELITIS

Until lately the view was fairly generally held, in poliomyelitis as in other infections, that immune body played an important rôle in resistance to infection Thus, convalescents as well as normal adults were presumed to be resistant largely because their sera contained antibody For example, it was suggested that effective resistance to infection was present if 0.5 c.c. of serum neutralized at least 10 minimum infecting doses of virus (Kolmer and Rule, 1935 *a*). *It is not now believed that poliomyelitis antibody plays any primary rôle in determining resistance to* infection Poliomyelitis can occur in persons with neutralizing antibody in the blood Antiserum is of no value in preventing the onset of paralysis. Further, experiments have rendered it evident that in the monkey resistance to infection is dependent on some alteration in the susceptibility of the nervous tissues, and not on the presence of antibody Schultz (1936) regards immune body as an adventitious by-product Some virus escapes into the blood and tissues and stimulates the production of antibody Antibody is an index of the attack of virus on nerve cells, and does not give protection The resistance enjoyed by normal adults or convalescents is alike attributable to previous contact with the virus, sufficient to render the nerve cells insusceptible In man as in the monkey, it is almost certain that some invasion by virus occurs in resistant persons, yet this does not progress far enough to cause serious lesions

been more or less restricted to the preparalytic stage in the hope of aborting the onset of paralysis

Dose. In the earlier days about 10 c c. used to be given on several occasions More recently workers have used doses of 20 c c or more intrathecally, combined with 50 c.c. intravenously; up to 50 c.c. can be given intramuscularly.

A valuable adjunct is to inject hypertonic saline intravenously as well as the serum, thus tending to lower intracranial tension and lessen edema and pressure (Aycock and Amoss, 1923).

Preservation and storage. The serum may be heated to 55° C. for half an hour, or treated with 0.2 per cent. tricresol (Amoss and Chesney, 1917) or 0 2 per cent phenol (Brodie, 1934 *c*), but a better method would appear to be that of Morgan

Morgan's method. This method has been used in Australia (Morgan, 1927, 1928, Burnet and Macnamara, 1929, Macnamara, 1929, Macnamara and Morgan, 1932). Blood is withdrawn into oxalate and after
calcium chloride is added to cause clottin
filter (EK), and after a second filtration,
into ampules This product is free from any antiseptic and is readily tolerated by children.

Another convenient method of storage would be to desiccate, as used by Madsen and Jensen (1936). After one year's storage of serum preserved with 0 2 per cent phenol, only 20 per cent. of the neutralizing power was lost (Brodie, 1934 *c*). After 2 years' storage, 50 per cent. had been lost, and finally after 4 years', only 25 per cent. of the original neutralizing power remained. Burnet and Macnamara (1929) reported that serum sealed in ampules without antiseptic could be stored for 3 years without significant loss of properties.

Results: (a) relatively uncontrolled.

Numerous authors from all parts of the world have used immune serum, and it must be admitted that many have expressed satisfaction, they have reported the prevention of paralysis, falls of temperature, and clinical improvement dating from the inoculation Poliomyelitis is a capricious disease and unfortunately very few of the authors to be mentioned have carried out adequate controls (Netter, Gendron, and Touraine, 1911, Netter, 1915, Amoss and Chesney, 1917, Fischer, 1917; Shaw, Thelander, and Fleischner, 1925, Aycock, Luther, and Kramer, 1929, Marinesco, Manicatide, and Draganesco, 1929, Macnamara, 1929, Faber, 1931, Levinson, McDougall, and Thalhimer, 1932, Macnamara and Morgan, 1932; Petter, 1933; Pohlen, 1934, 1936 *a*, Jensen, 1934–5, Hegler, 1936, Jackson, 1937, Kauders, 1937 *b*, Cadham, 1942).

Harmon (1934) has published a lengthy article which should be read by all interested in this subject He analyzes the published reports of some 4,400 treated and 2,660 untreated cases He stresses the failure of statistical presentation to demonstrate the value of serum, and finds that the outcome in treated preparalytic cases does not differ from the average for untreated patients He allows, however, from clinical observations that the serum may have some value.

(b) Controlled.

The great majority of published reports has not been free from the criticism that there were insufficient controls, and in fact in many series there were none at *all* Numerous authors have expressed dissatisfaction with the use of serum, but again these results were often not well controlled, and carried little weight The most important controlled observation on the value of serum, given in the preparalytic stage, was carried out in New York in the 1931 epidemic by the Health Department and the Academy of Medicine, the results were reported by Park (1932) and Fischer (1934) Thus, Fischer reported on 447 treated and 102 control patients

SECTION 10. VIRUS MENINGITIS

CHAPTER LXXXIX

ACUTE LYMPHOCYTIC CHORIOMENINGITIS

In 1934, Armstrong and Lillie, investigating St. Louis encephalitis by inoculating monkeys, isolated a virus that they called the "virus of lymphocytic choriomeningitis" (LCM). In addition to causing infection in mice and monkeys, numerous workers have isolated Armstrong's virus from cases of benign "aseptic" meningitis, and there is no doubt that it is the commonest individual cause of this condition (Armstrong and Wooley, 1935, Rivers and Scott, 1935, 1936, Scott and Rivers, 1936, Findlay, Alcock, and Stern, 1936, Barker and Ford, 1937, Lépine and Sautter, 1938, Armstrong and Sweet, 1939, Howard, 1939, MacCallum and Findlay, 1939, Findlay, Stuart-Harris, and MacCallum, 1940). However, the virus is not the sole cause of aseptic meningitis, and a similar clinical syndrome can occur in bacterial and other viral infections (Eckstein, Holtinger, and Schlerssing, 1932; Schneider, 1935; Rivers and Scott, 1936, Armstrong and Wooley, 1937, Baird and Rivers, 1938, Christie, 1943, Avery, 1945, Klopstock, 1945). The viral infections in which the syndrome of aseptic meningitis may occur include: mumps, measles, varicella, herpes zoster and febrilis, poliomyelitis, lymphogranuloma, and sandfly fever. A similar syndrome may occur in glandular fever (Tidy, 1946), hepatitis, and swineherd's disease (see below).

Many authors have published clinical descriptions of cases of aseptic meningitis, and some at least of these have been additional examples of infection with the virus of LCM (Wallgren, 1925, 1926, 1927, Viets and Watts, 1929, 1934, Dereux, 1931, Eckstein, 1931, Gibbens, 1931, Dickens, 1932, Armstrong and Dickens, 1935, Allen and Spencer, 1935, Collis, 1935, Birch, 1936, Burgers, 1936, McLean, 1936, Riesman, 1936, Hughes, 1937, Sreenivasan, 1940, Jennings, 1947) Useful general reviews on lymphocytic choriomeningitis have been published by Kreis (1937) and Farmer and Janeway (1942)

FEATURES OF HUMAN INFECTION WITH LCM VIRUS

The incubation period is probably from 1 to 3 weeks Prodromal symptoms are common, may last 7–20 days, and include remittent fever, chills, influenza-like symptoms, sore throat and tonsillitis, cough, and bronchitis (Farmer and Janeway, 1942) Then the typical meningeal symptoms develop, with headache, vomiting, stiffness of the neck, and photophobia The course is usually short and the majority of cases recovers in a few weeks In some instances the infection may recrudesce, even up to a total of

It is now known rm of illness, other syndromes may 1942; Milzer, 1943) In some cases ental changes, aphasia, diplopia, and paralysis (Findlay, Alcock, and Stern, 1936, Farmer and Janeway, 1942) In other cases, the illness is of an influenzal nature with viremia, but without clinical evidence of localization of virus in the CNS (Armstrong and Hornibrook, 1941). Smadel *et al* (1942) described a case of apparent virus pneumonia.

Labo

contam

(Milzer and Levinson, 1942; Smadel *et al.*, 1942; Yamarat, see Farmer and Janeway, 1942; Hayes and Hartman, 1943). The route of infection in these patients has been obscure, but probably the conjunctiva, respiratory tract, or skin has been the portal of entry

Clinical pathology. Leukopenia is commonly observed in the early stages, and this is followed by polynucleosis. The cerebrospinal fluid shows an increase in lymphocytes up to 3,000 per c mm The protein is slightly increased, but the sugar and chloride are normal

Distribution of the virus. In all types of infection, the virus is probably present in the blood in the early stages Later it invades the central nervous system, and is present in the CSF for the first 7–10 days of meningeal symptoms; it has been recovered in a relapsing case 13 weeks after the initial attack (Leichenger, Milzer, and Lack, 1940) The virus has been recovered from the CSF, even in the absence of definite pleocytosis (Milzer and Levinson, 1942, Treusch, Milzer, and Levinson, 1943). This virus may also be found in the nasopharynx (MacCallum and Findlay, 1939), and urine (Lépine and Sautter, 1938).

The pathological features have been described by various authors (Viets and Warren, 1937, Machella,
1940; Mitchell and Klotz,
cells, and macrophages.
inflamed Changes in the brain, and sometimes cord, include perivascular lymphocytic cuffing, hemorrhages, gliosis, and degeneration of nerve cells In one case chronic arachnoiditis developed and resulted in spastic paraplegia (Barker and Ford, 1937).

Laboratory diagnosis. Some cerebrospinal fluid (not over 0 03 c.c) should be injected intracerebrally in mice Precautions should be taken to insure that the mouse stock used is itself virus-free. Guinea-pigs should also be injected (intracerebrally or subcutaneously) The spleen of guinea-pigs or mice may be tested as early as 5–6 days after inoculation for fixation of complement with hyperimmune serum (Smadel and Wall, 1941). If available, a macaque may be injected cerebrally. Finally, the convalescent serum may be tested for the development of virus neutralizing and complement fixing antibodies, about 12 weeks after onset.

LYMPHOCYTIC CHORIOMENINGITIS IN MICE AND OTHER ANIMALS

Laboratory stocks of apparently healthy mice in all parts of the globe *are liable to* suffer from natural infection, and the presence of LCM virus must always be excluded when any new viral agent is isolated in mice, further, the virus may be passed in series
iboratory contaminant (Traub, 1935 *a*, *b*,
and Sautter, 1936) Mortality in infected
inimals show no symptoms, although the
sal secretions Many animals are resistant
s developing evidence of infection, such
ig, from 2–6 weeks old The intracerebral
inoculation of broth in infected animals induces the development of meningitis Histologically, naturally infected animals show mild meningeal infiltrations and focal necroses in the liver Traub (1939), examining a stock of mice infected with the virus for 4 years, found the infection to have become symptomless, infection took place by intra-uterine spread, and *not by contact*

LCM virus has been encountered in other animals Thus Dalldorf (1939 *b*) found that a strain of canine distemper passed in dogs and ferrets had become contaminated It has been encountered in monkeys (Armstrong and Wooley, 1935, Coggeshall, 1939) The virus appeared as a contaminant in cultures of rabies virus, where mouse brain and monkey serum were used (Casals-Ariet and Webster, 1940)

EPIDEMIOLOGY

Small outbreaks of aseptic meningitis have been described (Laubry and Foy, 1910, Rist and Rolland, 1910, Wallgren, 1925, Eckstein, 1931, Dummer, Lyon, and

Stevenson, 1937). It is very unlikely, however, that these outbreaks were associated with the LCM virus, for infections with this agent are invariably sporadic, and case to case transmission is virtually unknown

The disease occurs in all parts of the world.

The Routes and Sources of Infection

The route of infection is not definitely known. It is certain, however, that the virus can enter the body by the conjunctiva (Lépine and Sautter, 1938). It can probably also pass through the skin, or be inhaled in the form of infected droplets or dust particles (Findlay, Alcock, and Stern, 1936) Cases have been recorded following tonsillitis (Riesman, 1936). It has been suggested that the infection may be acquired venereally (Wooley, Armstrong, and Onstott, 1937).

Case to case infection is extremely rare, the possibility of human carriers infecting by means of droplets is remote.

Main suspicion falls on *mice* as the source of infection. As mentioned above, laboratory mice are very liable to be infected with the virus. Observations have shown that a considerable percentage of house mice, perhaps up to 20 per cent., caught in random samples in urban areas carry the virus, or prove resistant to challenge, embryos have been found infected (Armstrong, Wallace, and Ross, 1940, Yamarat, see Farmer and Janeway, 1942, Dalldorf, Jungeblut, and Umphlet, 1946). Probably mice caught in rural areas may also be infected (Howitt and van Herick, 1942). Further, the virus has been isolated from mice trapped in the homes of cases of the disease (Armstrong and Sweet, 1939, Armstrong, Wallace, and Ross, 1940). Dalldorf, Jungeblut, and Umphlet (1946) reported a small focus of 4 cases in close neighbors, and isolated virus from mice trapped in the dwelling.

Another point suggesting the rôle played by mice is the tendency for the greater incidence of cases in spring when the mice are breeding, and again in the autumn when colder weather drives them indoors (Armstrong, 1941).

The method of transmission of virus from mouse to man is probably by inhalation of dried urine A case has been reported where infection may have arisen through handling a dead infected mouse (Farmer and Janeway, 1942)

Mosquitoes have been incriminated, and on an analogy with virus encephalitis, might be expected to play some part. The evidence is, however, experimental rather than epidemiological Coggeshall (1939) showed that *Aedes* could transmit the infection to guinea-pigs as early as the 4th, and at least as late as the 15th day after feeding on an infected animal Milzer (1942) obtained similar results, when *Aedes* were incubated at temperatures between 26 and 37° C transmission was obtained from 7–38 days after the infective meal

Bedbugs can also transmit the infection to guinea-pigs, partly by bite, and partly by the rubbing in of infected feces (Milzer, 1942)

Lice have also been blamed The virus is retained for at least some hours in the human body louse fed on the infected monkey (Findlay, Stuart-Harris, and MacCallum, 1940) The monkey louse can transmit the infection to monkeys (Armstrong, 1941), and probably man (Milzer and Levinson, 1942)

The tick (Dermacentor andersoni) has been infected at all stages, and adult to egg transmission occurs, infection was transmitted to guinea-pigs by feeding nymphs which had engorged in their larval stage on an infected animal, infection was also transmitted by applying infected crushed ticks or tick feces to the scarified skin (Shaughnessy and Milzer, 1939).

The nematode Trichinella spiralis has been incriminated experimentally (Syverton, McCoy, and Koomen, 1947) The larvae after maturation in the muscles of infected guinea-pigs acquired the virus and could transmit it to new hosts, transmission resulted both when living larvae were fed to normal pigs and when triturated dead larvae were injected subcutaneously

(Milzer and Levinson, 1942, Smadel *et al.*, 1942, Yamarat, see Farmer and Janeway, 1942; Hayes and Hartman, 1943). The route of infection in these patients has been obscure, but probably the conjunctiva, respiratory tract, or skin has been the portal of entry.

Clinical pathology. Leukopenia is commonly observed in the early stages, and this is followed by polynucleosis. The cerebrospinal fluid shows an increase in lymphocytes up to 3,000 per c mm The protein is slightly increased, but the sugar and chloride are normal.

Distribution of the virus. In all types of infection, the virus is probably present in the blood in the early stages Later it invades the central nervous system, and is present in the CSF for the first 7–10 days of meningeal symptoms; it has been recovered in a relapsing case 13 weeks after the initial attack (Leichenger, Milzer, and Lack, *1940*). *The virus has been recovered from the CSF, even in the absence* of definite pleocytosis (Milzer and Levinson, 1942; Treusch, Milzer, and Levinson, 1943). This virus may also be found in the nasopharynx (MacCallum and Findlay, 1939), and urine (Lépine and Sautter, 1938).

The pathological features have been described by various authors (Viets and Warren, 1937, Machella, Weinberger, and Lippincott, *1939*, Silcott and Neubuerger, 1940, Mitchell and Klotz, 1942). The meninges are infiltrated with lymphocytes, red cells, and macrophages The choroid plexuses and ventricular ependyma may be inflamed. Changes in the brain, and sometimes cord, include perivascular lymphocytic cuffing, hemorrhages, gliosis, and degeneration of nerve cells. In one case chronic arachnoiditis developed and resulted in spastic paraplegia (Barker and Ford, 1937).

Laboratory diagnosis. Some cerebrospinal fluid (not over 0 03 c c) should be *injected intracerebrally in mice Precautions should be taken to insure that the* mouse stock used is itself virus-free. Guinea-pigs should also be injected (intracerebrally or subcutaneously). The spleen of guinea-pigs or mice may be tested as early as 5–6 days after inoculation for fixation of complement with hyperimmune serum (Smadel and Wall, 1941) If available, a macaque may be injected cerebrally Finally, the convalescent serum may be tested for the development of virus neutralizing and complement fixing antibodies, about 12 weeks after onset.

LYMPHOCYTIC CHORIOMENINGITIS IN MICE AND OTHER ANIMALS

Laboratory stocks of apparently healthy mice in all parts of the globe are liable to suffer from natural infection, and the presence of LCM virus must always be excluded when any new viral agent is isolated in mice, further, the virus may be passed in series unknowingly along with another agent, as a laboratory contaminant (Traub, 1935 *a*, *b*, 1936 *a*, *b*, Findlay,
mouse stocks is le
virus is present in
to challenge with ...
as emaciation, drowsiness, and ruffled fur, are young, from 2–6 weeks old The intracerebral inoculation of broth in infected animals induces the development of meningitis Histologically, naturally infected animals show mild meningeal infiltrations and focal necroses in the liver Traub (1939), examining a stock of mice infected with the virus for 4 years, found the infection to have become symptomless, infection took place by intra-uterine spread, and not by contact

LCM virus has been encountered in other animals Thus Dalldorf (1939 *b*) found that a strain of canine distemper passed in dogs and ferrets had become contaminated *It has* been encountered in monkeys (Armstrong and Wooley, 1935, Coggeshall, 1939) The virus appeared as a contaminant in cultures of rabies virus, where mouse brain and monkey serum were used (Casals Ariet and Webster, 1940)

EPIDEMIOLOGY

Small outbreaks of aseptic meningitis have been described (Laubry and Foy, 1910, Rist and Rolland, 1910, Wallgren, 1925, Eckstein, 1931, Dummer, Lyon, and

necrosis of liver, thymus, spleen, lymph nodes, and marrow, thrombi in liver and other viscera, and lymphocytic infiltrations in the pleura, peritoneum, renal cortex and pelvis, liver, salivary glands, pancreas, thoracic organs, and adrenals

Traub (1938 *b*) has reported that mice may become infected *in utero*, or during suckling, animals infected *in utero* carried virus in the blood longer than those infected during suckling. In mice infected during suckling or after intranasal instillation, it was the younger ones that remained carriers for the longer time Haas (1941) found that mice infected *in utero* or early infancy retained active virus for long periods, and transmitted infection to offspring and contacts Mice infected when mature did not transmit infection to offspring, except when the animals were pregnant at the time of inoculation.

Rabbits.

Rabbits show no symptoms after introduction of virus by the usual routes, but become actively immune (Findlay and Stern, 1936, Traub, 1936 *a*, Rivers and Scott, 1936).

Guinea-pigs.

These animals can be infected readily by cerebral or peripheral routes (Findlay and Stern, 1936; Rivers and Scott, 1936, Scott and Rivers, 1936, Traub, 1936 *a*, *b*, Lépine, Kreis, and Sautter, 1937, Ronse, 1937, Mendoza, 1937) Viremia develops 24 hours after inoculation, and persists till death (Shaughnessy and Milzer, 1939, Milzer, 1942). The virus is firmly bound to the red cells (Shwartzman, 1943, 1946)

The pathological features have been fully described by Lillie and Armstrong (1944): There is a relatively mild and chiefly basilar lymphocytic meningitis and focal lymphocytic infiltration of the choroid plexus. Foci of lymphocytic infiltration occur in the heart and lungs, and perhaps other organs Focal necrotic and proliferative lesions occur in the liver. The spleen shows an early polymorph infiltration, with later a reticulo-endotheliosis and lymphoid cell infiltration. Follicle hyperplasia occurs in the spleen, lymph nodes, and intestinal lymphoid tissue

After intracerebral injection, the majority of animals dies from a mild meningitis with "virus" pneumonia. After serial passage through mice, Traub (1937) attenuated a strain so that, on intracerebral injection, it produced only fever.

After subcutaneous and, less commonly, after intraperitoneal injection fever develops, the animal salivates, becomes emaciated, and finally dies in 9 to 16 days Virus may be found in the blood and hemopoietic system, brain, urine, and lungs. It persists in the urine for some weeks after recovery, but not in the blood (Traub, 1936 *b*) Infection can also take place through scarified or even unbroken skin (Shaughnessy and Milzer, 1939, Shaughnessy and Zichis, 1939, 1940).

Other rodents.

After intracerebral injection, rats may die from choriomeningitis, but this is uncommon After intraperitoneal and other peripheral injections no symptoms are manifest, although antibodies may develop and the virus be recoverable from the blood, brain, liver, spleen, and urine (Findlay and Stern, 1936, Traub, 1936 *a*, Lépine, Kreis, and Sautter, 1937). *Sigmodon* and *Microtus* can be infected (Howitt and van Herick, 1941), also Syrian hamsters (Smadel and Wall, 1942).

Monkeys.

N[illegible]

L[illegible]

a[illegible]

A[illegible]

The temperature rises 4 to 8 days after intracerebral injection and remains up (104° F.) for 3 to 10 days, the animal goes off its food, loses weight, is very quiet

PROPERTIES OF THE VIRUS

There is no evidence that different antigenic types exist (see, e g, Milzer and Levinson, 1942).

Human Inoculation Experiments

Lépine, Mollaret, and Kreis (1937) inoculated human beings subcutaneously. Fever of an undulant type developed after 36 to 48 hours and lasted for up to 3 weeks; the clinical features resembled influenza. About half the patients showed a definite meningeal reaction with abrupt onset of headache, vomiting, and Kernig's sign. The virus was demonstrated in the blood and cerebrospinal fluid.

Animal Experiments

Guinea-pigs and mice are chiefly used for the isolation of virus and its passage in the laboratory. Shwartzman (1946) studied the viscero- and neuro-tropic properties of substrains passed in series through guinea-pigs and mice All substrains were neurotropic for the mouse, irrespective of the animal used for previous passage. Viscerotropism was acquired by serial passage through the guinea-pig, and lost on serial passage through the mouse.

Mice.

Mice can be infected readily (Armstrong and Lillie, 1934, Armstrong and Wooley, 1935; Rivers and Scott, 1936, Findlay, Alcock, and Stern, 1936, Findlay and Stern, 1936, Lépine and Sautter, 1936, Traub, 1936 *a*, *b*, Lépine, Kreis, and Sautter, 1937, Ronse, 1937). Young mice are more susceptible than older animals, especially to peritoneal inoculation (Casals-Ariet and Webster, 1940). Young mice tend to retain virus for life, whereas it is difficult to demonstrate virus in older mice, except shortly after inoculation (Haas, 1941). Viremia commonly develops 24 hours after inoculation, and persists for at least 7 days, following cerebral, subcutaneous, or peritoneal inoculation (Milzer, 1942) Strains of high virulence for the mouse show a firm association of virus with the red cells (Shwartzman, 1943, 1944, 1946) The pathology has been fully described by Lillie and Armstrong (1945)

Intracerebral injection. Mice show evidence of infection on the 6th to 7th day, the fur is ruffled, there are coarse tremors of the head, and if the animal is picked up by the tail, it makes very rapid convulsive movements, which last for a matter of seconds or up to a minute. In the later stages these convulsions occur frequently without outside stimulation. The animal usually dies in 1 to 3 days.

Histologically, the brain shows an abundant lymphocytic infiltration of the meninges with occasional hemorrhages most marked basally The plexuses show abundant exudate and there is some glial proliferation of the walls of the lateral ventricles The ventricles themselves are filled with lymphocytes, plasma cells, and some polymorphs. There is little nerve cell destruction, and perivascular cuffing is only marked near the ventricles

Focal necrotic lesions are found in the liver and spleen Apart from the brain the virus is to be found in whole blood, plasma, urine, spleen, liver, lungs, kidneys, and adrenals

Nasal instillation Encephalitis develops after nasal instillation

Other routes of infection An indefinite nonfatal illness with development of immunity follows the introduction of virus by the following routes scarification of skin, subcutaneous, intraperitoneal, intravenous, and instillation of the external ear. Contact infection can occur Even after peripheral inoculation, the brain may show changes, visceral lesions, infrequent after cerebral inoculation, are more pronounced when other routes are used (Lillie and Armstrong, 1945). The following changes have been observed polyserositis, fatty degeneration of liver and kidneys, focal

1941), or an extract irradiated with UVL (Casals, 1942; Havens *et al.*, 1943). Complement fixing antisera can be prepared readily in hyperimmune guinea-pigs.

Complement fixation depends partly on the elementary body, but more particularly on a soluble substance (Smadel, Baird, and Wall, 1939 *a*, *b*). The properties of this soluble substance are as follows (1) SS can be separated from virus, by centrifugation and Seitz filtration, washed virus fixes complement poorly, SS is widely distributed in the tissues, especially the spleen and brain, of infected guinea-pigs, mice, and monkeys (Smadel, Baird, and Wall, 1939 *b*) (2) SS is relatively stable, and resists 56° C. for ½ hour, it is of protein nature (Smadel, Wall, and Baird, 1940). (3) Precipitation occurs when serum is added to solutions of antigen (Smadel, Wall, and Baird, 1940). (4) SS can be kept in solution in the refrigerator for months, or it can be stored if dried from the frozen state (Smadel and Wall, 1941) It resists irradiation (Havens *et al*, 1943) (5) Formalin-treated virus-free extracts, containing large amounts of SS, fail to elicit antibodies to SS (or to induce resistance) in normal guinea-pigs, when administered to immune guinea-pigs, however, there is a marked increase in the titer of anti-SS substance. On the other hand, suspensions of formolized washed virus are effective in normal guinea-pigs in stimulating the development of both anti-SS and neutralizing substances, and inducing resistance (Smadel and Wall, 1940)

Virus neutralization has also been studied, and hyperimmune animal or convalescent human sera neutralize the infectivity of virus, serum-virus mixtures are usually inoculated cerebrally in mice or subcutaneously in guinea-pigs (Armstrong ... 'ey, 1935; Lépine and Sautter, 1936; Findlay, ... :ott, 1936, Scott and Rivers, 1936; Traub, ... Armstrong, and Onstott, 1937, Howard, 1939, ... 1939, ... and Levinson, 1942).

The interrelationship of the various antigen-antibody reactions is as follows Precipitation and complement fixation are dependent on the interaction of SS with the same antibody, but the neutralizing antibody appears to be separate (Smadel and Wall, 1940, Smadel, Wall, and Baird, 1940).

Active Immunity

Guinea-pigs can be rendered partly resistant by injection of formolized virus (Traub, 1938 *a*, Smadel and Wall, 1940).

Mice can be rendered resistant by peripheral injection of live virus (Traub, 1938 *b*, Casals-Ariet and Webster, 1940, Lyon, 1940)

Antibody Response in Man

nor ... ma ... bee ... Milzer, and Levinson, 1943).

On recovery from infection, neutralizing antibodies develop rather slowly, and have been detected at 8 weeks from onset, the titer increases to a maximum about 6 months after onset, and reaches a constant level after 12 months, which is maintained for a considerable period (Farmer and Janeway, 1942, Milzer and Levinson, 1942)

C ... r, and have been detected 3–5 ... at least 2 years (Farmer and ...

RELATIONSHIP TO OTHER VIRUSES

There is no relationship between LCM and the following viruses influenza or LGI virus (Traub, 1936 *a*), Durand's virus (Findlay, 1942), Japanese, St Louis, West Nile, western or eastern equine encephalomyelitis viruses (Howitt, 1936–7,

and apathetic, and may show intention tremors of the hands; death may result, but certain animals recover and show active immunity. The cerebrospinal fluid shows a lymphocytosis and the blood a polynucleosis. Monkeys can also be infected *intraperitoneally*, but *encephalitis does not develop*. *Armstrong, Wooley, and* Onstott (1936) found virus in brain, spinal cord, and cerebrospinal fluid, blood, adrenals, kidneys, liver, lungs, lymph nodes, marrow, heart, voluntary muscle, pancreas, spleen, and testicles. Lillie (*1936 b*) reports the histological features in infected monkeys as follows. lymphocytic infiltration of the plexuses and meninges, some perivascular infiltration in brain and cord, focal lymphocytic infiltration in root ganglia, congestion and interstitial edema of the lungs; pyelitis and hemorrhagic cystitis; focal hepatic necrosis, and lymphocytic infiltration of the heart, testis, muscles, and abdominal organs.

Insusceptible animals.

Chicks, pigeons, dogs, ferrets, hedgehogs, voles, hens, canaries, and parakeets show no symptoms (Traub, *1936 a*; Findlay, Alcock, and Stern, *1936*).

Chemotherapy

Prontosil was stated to have a protective effect against infection in mice when injections were begun early in the incubation period (Rosenthal, Wooley, and Bauer, 1937), other authors, however, have not confirmed these findings (see MacCallum and Findlay, 1938, McKinley, Meck, and Acree, 1939, Toomey and Takacs, 1944)

Morphology and Cultivation

The virus probably measures between 33 and 60 mμ, as determined by filtration or centrifugation (Rivers and Scott, *1936*, Scott and Elford, *1939*, Casals-Ariet and Webster, *1940*) It passes the following filters Berkefeld V, N, and W, Chamberland L_1, L_2, L_3, Seitz EK (Armstrong and Lillie, *1934*; Rivers and Scott, *1936*, Findlay, Alcock, and Stern, *1936*; Lépine, Kreis, and Sautter, *1937*).

The virus can be cultivated on the chorio-allantois (*Bengtson and Wooley*, *1936*, Tubaki, *1940*, Milzer and Levinson, *1942*). However, no characteristic pocks or other lesions develop, and there are no specific lesions (Lillie, *1936 a*)

It can be cultivated in minced chick or mouse embryo, serum, and Tyrode (MacCallum and Findlay, *1940*, Casals-Ariet and Webster, *1940*)

Reaction to Physical and Chemical Agents

The virus resists 50 per cent. neutral glycerol for at least 7 months. It maintains its virulence at 5° C in a suspension under a vaseline seal for at least 2 months, and in a Petri dish for 1 month After desiccation from the frozen state it remains active for at least 12 months The virus is destroyed by 55° C in 20 minutes (Armstrong and Lillie, 1934, Findlay, Alcock, and Stern, 1936, Rivers and Scott, 1936, Lépine, Sautter, and Kreis, 1937, Wooley, 1939) It is rapidly inactivated by UVL (Havens *et al*, 1943) It is inactivated by various fatty acids and detergents (Stock and Francis, 1943).

IMMUNITY

Antigen-Antibody Reactions

Complement fixation can be demonstrated readily between suspensions of infected tissues and animal or human hyperimmune or convalescent serum (Howitt, 1936–7, Lépine and Sautter, 1938, Lépine, Mollaret, and Sautter, 1938, Milzer and Levinson, 1942).

Various types of antigen can be used e g, a saline extract of infected spleen, an extract of infected brain prepared by freezing and thawing (Casals and Palacios,

1937; Milzer and Levinson, 1942; Havens *et al*, 1943); feline agranulocytosis virus (Lawrence *et al.*, 1943); EKC virus (Sanders and Alexander, 1943). Dalldorf (1939 *a*) detected a sparing effect, partly reciprocal, between LCM, and poliomyelitis in monkeys.

THE VIRUS OF PSEUDOLYMPHOCYTIC CHORIOMENINGITIS

MacCallum, Findlay, and Scott (1939) gave this name to a virus isolated on two occasions from the cerebrospinal fluid of patients suffering from benign aseptic lymphocytic meningitis. It resembles LCM closely, except that in mice the incubation period is only 4 to 5 days, and the lesions are less extensive.

SWINEHERD'S DISEASE

This disease is also known as *maladie des porchers*, or eruptive meningotyphoid, and is characterized by a febrile period with gastro-intestinal disorder and a rash, followed by a remission, after which meningeal signs develop (see Penso, 1936). It occurs chiefly in France, Italy, and Switzerland in swineherds and others who come into close contact with sick pigs Infection appears to be contracted from these animals, perhaps by the excreta, and not from human cases. The infection appears to be transmissible to man by inoculation of blood (Durand *et al*, 1937, Georgi, Pache, and Urech, 1938) Claims have been made that the causal agent is a filtrable virus transmissible to animals (*e.g*, Durand *et al*, 1936, Penso and Rosa, 1938), but insufficient work has yet been carried out.

HUMPHREYS' VIRUS

This strain was isolated in guinea-pigs inoculated with a suspension of ticks (Humphreys, Helmer, and Gibbons, 1944) It was highly pathogenic for guinea-pigs, and grew in the chick embryo. The histological lesions show less necrosis, edema, and fibrin, and more lymphocytic infiltration, but otherwise correspond to those obtained in LCM infection (Lillie and Armstrong, 1945). Perrin and Steinhaus (1944) also remarked on histological differences. It does not appear to be possible on the evidence available to decide whether this virus is identical with LCM, but it is certainly closely related

CHAPTER XC

DURAND'S VIRUS

This was isolated by Durand (1940) from his blood during a febrile illness in 1939 The main symptoms were fever, constipation, and insomnia The illness lasted 11 days, and was followed by asthenia before complete recovery. A virus known as "D" was isolated by intraperitoneal inoculation in guinea-pigs, and the strain was passed in series. D virus has also been studied by Findlay (1942).

Infection in Man

Experimental inoculation produces a local reaction, headache, fever, and viremia, the CSF may contain virus (Durand).

Findlay described a laboratory infection characterized by nasal catarrh, dry cough, lethargy, fever, headache, vomiting, and loss of weight. Virus was isolated from the blood

Infection in Animals

Guinea-pigs can be infected by the peritoneal, subcutaneous, cutaneous, muscular, testicular, nasal, cerebral, and ocular routes (Durand, Findlay). The most characteristic lesions are found following subcutaneous injection. The incubation period varies from 3–10 days, largely according to the amount of virus inoculated Illness is characterized by fever, lasting 6–10 days There is a local inflammatory reaction at the site of inoculation, with regional adenitis The animal is generally "off-color," and develops conjunctivitis and dyspnea Loss of weight is considerable Animals usually recover, but death may occur from rupture of the spleen, or generalized lesions. Autopsy shows evidence of loss of weight, there is hemorrhagic edema at the site of inoculation, with lymphadenitis, the spleen is enlarged, the lungs are congested and show interstitial pneumonia (Durand, Findlay). The in-

Properties of the Virus

The virus passes a Chamberland L_2 candle, a Seitz EK pad, and all grades of Berkefeld filter, the size, determined by filtration, is between 53 and 80 mμ, it can be kept in the ice chest for some weeks, it can be preserved in glycerine, or by freezing and drying (Durand, Findlay).

Findlay cultivated the virus in chick embryo tissue in serum and Tyrode; he also found that virus generalized in the egg and might cause death after yolk sac or chorio-allantoic inoculation

Immunity

Recovered guinea-pigs are immune to reinfection from 3 weeks after the end of the febrile period, and this resistance lasts for several months, immunity can be induced with killed virus (Durand, Findlay)

In convalescence, virus-neutralizing antibodies develop in man, rabbits, guinea-pigs, and other animals, complement fixation can also be demonstrated (Durand; Findlay).

Relationship to Other Viruses

Findlay found no evidence of cross immunity between virus D and LGI or LCM

myelitis is the primary manifestation of infection, and which will be discussed in the following pages The causal agents of encephalitis lethargica and Australian X disease have not been isolated, but are presumed to be viruses. Encephalitis can be produced by the following neurotropic viruses St Louis, Japanese, Russian, North and South American equine encephalomyelitis, and louping ill Certain viruses, e g, the West Nile virus, isolated by yellow fever workers (see Section 4) are also neurotropic in animals, but at present we do not feel that enough is known of their pathology in man to justify their classification in this section

For the sake of completeness we should mention that the specific neurotropic infections poliomyelitis and rabies have already been discussed in special sections, and so have the infections characterized by meningitis rather than encephalitis

Finally, various outbreaks and sporadic cases of encephalitis have been described, where it appears highly likely that a virus is concerned. For various reasons, however, no special virus studies have been made. Such cases have occurred in the following areas: in South Central Africa and Kenya (Charters, 1940, Berney and Gelfand, 1946); in the Argentine (Valdes, 1943); in troops in N. Australia, Horan *et al.* (1944) described 2 fatal cases due to an unknown agent entering peripherally, spreading by nerve paths, and producing focal necroses of the nervous tissues and of the walls of small and medium veins, in Brazil (Di Lascio, 1943), in Germany (Gildemeister and Haagen, 1940), in India (Chatterji, Gupta, and De, 1945); in Sweden (Moller, 1939), and in Texas (Woodland and Smith, 1942).

SECTION 11. DISEASES CHARACTERIZED CHIEFLY BY ENCEPHALITIS, ENCEPHALOMYELITIS, OR MYELITIS

CHAPTER XCI

THE ENCEPHALITIS GROUP OF VIRUSES: INTRODUCTORY

ENCEPHALITIS and encephalomyelitis occur in various circumstances, and although we are concerned only with virus infections, it is desirable first to mention some other types of known as well as of uncertain etiology.

For example, encep[illegible] meningo-cocci, and may occur [illegible] the exhibition of ent[illegible] amides (Brain, 1943).

Histological changes similar to those seen in infective encephalitis may be produced by carbon monoxide poisoning, brain injury, arteriosclerosis, uremia, pregnancy toxemia, and toxic agents like alcohol and lead (Toomey, 1940, Putnam, 1941)

Although we cannot enter into the vexed question of the etiology of disseminated sclerosis, it is of interest to note that it has been claimed recently that some cases may be of virus origin (Margulis, Soloviev, and Shubladze, 1946). Further, it has been reported that disseminated sclerosis developed in 4 out of 7 workers studying the disease of lambs known as sway-back (Campbell *et al.*, 1947), this disease is associated with demyelination. There has hitherto been no definite evidence that sway-back is due to a virus, and copper deficiency appears to be of importance. These new observations, however, show that the question requires fresh consideration

Another interesting disease of uncertain etiology is known as "acute hemorrhagic leuko-encephalitis" (Hurst, 1941, Henson and Russell, 1942, Greenfield, 1943, Russell, 1943, Shallard and Latham, 1945). It is characterized by rapid loss of higher functions, and histologically by severe damage to the walls of blood vessels, perivascular necrosis, focal and perivascular demyelination, marked polymorph infiltration, microgliosis, edema, and hemorrhages.

Encephalitis may be produced by the causal agents, probably viruses, of glandular fever and infectious hepatitis (Thelander and Shaw, 1941, Brain, 1943)

A type of encephalitis that may be due to a virus is that known as "inclusion" encephalitis There are acidophilic intranuclear inclusions like those of herpes in the ganglionic cells of the cortex (Brain, 1943, Greenfield, 1943, Russell, 1943)

A disease from which a virus has been isolated is that known as "acute primary [illegible] encephalitis" occurring in Russia and other parts of Europe [illegible] 1944)

[illegible] virus infections, encephalitis and encephalomyelitis may occur as complications of the following, most of which are fully discussed elsewhere in this book variola, varicella, mumps, rubella, measles, influenza, *herpes febrilis*, herpes zoster, as well as rickettsial diseases Encephalomyelitis may follow the inoculation of rabies vaccine or vaccinial lymph Perivascular demyelination is a characteristic finding in many of these conditions

There is also a large number of virus diseases where encephalitis or encephalo-

mentioned, these contain nearly every reference to published work and should be consulted for fuller information than can be given in this chapter.

Clinical Features

The incubation period varied from 3 to 21 days, the usual interval being 10 to 14 (Parsons, MacNalty, and Perdrau, 1922). *Prodromal symptoms* of lethargy, insomnia, headache, vertigo, dry mouth, constipation, hiccup, dysuria, tremors, diplopia, tinnitus, and severe pains might occur; the temperature often rose, to fall in the course of a few days (Bramwell, 1921). *The onset* of the disease proper occurred in one of four ways (*a*) asthenic or somnolent type; (*b*) the meningitic type, (*c*) apoplectiform type, (*d*) with neuralgia referred to one or more extremities, or the head (Bramwell and Miller, 1920). MacNalty (1918) described the manifestations of the established disease as follows

General symptoms Conjunctivitis, headache, vomiting, pyrexia, sweating, skin eruptions, and edema might all occur. These symptoms were usually [illegible] with one or more features indicative [illegible]

centr[illegible]

ters [illegible]

oph[illegible] [illegible], strabismus, diplopia, and bilat[illegible] [illegible] palsies were all observed The 7th nerve was sometimes affected, giving a bilateral facial paralysis. The various motor nuclei of the lower cranial nerves might be attacked, giving, for instance, aphonia The face was characteristically impassive and mask-like

Certain cases of acute febrile chorea were described (particularly in France) which were true cases of encephalitis lethargica (see Brouardel, Levaditi, and Forestier, 1920, Levaditi and Harvier, 1920 *e*) Epidemics of hiccup were observed in various parts of the world (see Boyd, 1920 *a*, *b*, Parsons, MacNalty, and Perdrau, 1922), coexistent with the epidemic of encephalitis [illegible]

was due to a [illegible]

In childre[illegible]

palsy de[illegible]

were c[illegible]

Wal[illegible] [illegible] of encephalitis had a complex action on the central nervous system Either its action was a paralyzing one, affecting only the basal ganglia or brain stem, or it was irritant, when it affected any and every part of the central nervous system This theory certainly explains the varied nature of the nervous manifestations

Clinical Pathology

Acute stage The [illegible] authors (see, e g, Netter, 1920 *a*, [illegible], and Perdrau, 1922). The cell coun[illegible] [illegible] in proportion to the severity of the infection and although seldom more than 20 to 30 cells per c mm. were found, counts up to 90 were recorded on occasions. In almost every case the increase was due to a lymphocytosis Sugar was occasionally increased up to 0 1 per cent (Netter, 1920 *a*, Foster, 1921) Total protein showed a small increase in many cases (Parsons, MacNalty, and Perdrau, 1922) Colloidal gold curves were frequently luetic and less commonly paretic in type (Findlay and Shiskin, 1921, see also Douglas, 1926)

Chronic stage According to Parsons, MacNalty, and Perdrau, the cerebrospinal fluid was normal except for slight inconstant increases in the number of lymphocytes, total protein, and chloride content

CHAPTER XCII

ENCEPHALITIS LETHARGICA

Historical

In the 16th, 17th, 18th, and 19th centuries there were numerous outbreaks in Europe of a disease characterized by somnolence So pronounced a feature was this, that the disease became known as sleepy sickness, *Schlafkrankheit*, or *nona*, according to the country affected. Full accounts of these early outbreaks, which were probably due to encephalitis lethargica, are to be found in various papers (Netter, 1920 *a*, *b*, Zinsser, 1928, Abrahamson, 1935).

Modern interest in encephalitis lethargica only dates from World War I, when the disease was first described independently in France by Cruchet, Montier, and Calmettes (1917), and in Austria by von Economo (1917). The main clinical features of these outbreaks were somnolence, oculomotor palsies, signs of cerebral and meningeal irritation, and pyrexia. It was recognized at once that this disease was to all intents new

[illegible]

due to a cultivable organism

The disease soon assumed pandemic distribution and the first cases in England were recorded by Harris (1918) and Hall (1918 *a*, *b*) At this early stage the features were those of drowsiness, pyrexia, and ophthalmoplegia, and therefore the question of botulism naturally arose, especially in view of the nature of the foodstuffs available toward the end of the war. It was soon found, however, that the disease was not due to any form of food poisoning but was a specific entity (*Rep. loc. Govt Board*, N S 121, 1918)

Netter (1918, see also 1920 *a*, 1921 *a*, *b*) described some of the early cases in France. The disease appeared in the Far East in 1919 and spread rapidly (see Pfister, 1929). The early cases in America were reviewed by Bassoe (1919) and Smith (1921). In Canada, Boyd (1920 *a*, *b*) described an outbreak in Winnipeg By 1920 the disease had assumed a world-wide distribution

FEATURES OF ENCEPHALITIS LETHARGICA AS SEEN FROM 1918 TO 1920

Incidence of the Disease in the British Isles

The disease was made compulsorily notifiable as from January 1, 1919, in England and Wales, and in 1919 the number of cases thus reported was 541 In 1921 this figure had risen to 1,470 A temporary abatement occurred in 1922 (454 cases), but the disease broke out again in 1923 (1,025 cases), and assumed its most serious proportions in 1924 (5,039 cases) From that time onward the numbers of notifications have gradually fallen as follows 1925—2,635 cases, 1928—1,308 cases, 1931—651 cases, 1934—411 cases, 1936—269 cases, 1937—217 cases

The disease was made the subject of a number of official reports, the main findings of which are described later (*Rep loc Govt Board*, N S. 121, 1918, *Suppl 48th Ann Rep. loc Govt Board*, London, 1919, *Ann Rep. Chief M O Min Hlth*, Append. 7, London, 1919–20, *Rep publ Hlth med Subj*, no 11, London, 1922, *Med res Counc spec Rep*, no 108, London, 1926)

In addition, the surveys of the Matheson Commission (1929, 1932) should be

temporary incapacity months before. The general symptoms are usually restricted to those of pyrexia. Nervous manifestations are varied, and include paralyses of the cranial nerves (especially ophthalmoplegias), irritative twitchings, oculogyric crises, and choreiform movements. Lethargy is usually found only in cases showing paralysis

At the same time it must be realized that the disease may present itself in any of the "types" already described.

It has been estimated that approximately one-third of patients recover from the acute attack only to develop characteristic sequelae of which parkinsonism is the commonest

According to Lapage (1933) the main features of encephalitis lethargica in childhood are as follows Lethargy is commonly found, deepening into coma in severe cases Headache is common and very persistent. Although diplopia may be present the child may not actually complain. Hiccup is a common symptom, and myoclonic and paralytic cases may occur. Sequelae are common and take the form of [illegible] the [illegible] the

PATHOLOGY

A. Acute Infections of the Central Nervous System

Naked-eye, there is frequently a diffuse pinkness of the brain, and on section small pin point hemorrhages may be found in the gray matter. There is not, however, any particularly diagnostic feature and, in fact, the brain often appears quite normal to the naked eye.

Microscopically, Marinesco (1918 *a*, *b*) reported on some of the first cases of the disease that occurred in Great Britain, numerous others have also published descriptions (e g, von Economo, 1917, von Wiesner, 1917, Marie and Trétiakoff, 1918, Boyd, 1920 *a*, *b*, Bramwell and Miller, 1920, Levaditi and Harvier, 1920 *e*, MacNalty, 1921, Hume, Nattrass, and Sh[illegible].

The characteristic lesions are usually [illegible] ing regions, and are most marked in th[illegible] aqueduct of Sylvius, 3rd ventricle, posterior part of pons and peduncles, and to a limited extent in the upper part of the cord These lesions are of a number of types

1 Infiltration of the adventitial coats of the smaller vessels (especially venules) with lymphocytes and plasma cells. In the more acute cases there are large numbers of polymorphs to be found, even constituting miliary abscesses (Hume, Nattrass, and Shaw, 1922)

2. Foci of interstitial inflammation, consisting of neuroglia with large excentric nuclei and sometimes fibrillary projections, are present

3 Lesions of the nerve cells take the form of lysis of the Nissl bodies, satellitosis, *and reduction in the volume of the cell body* and the number of its processes There is a notable diminution in the number of nerve cells in the dorsal nucleus of the vagus, locus ceruleus, and locus niger. Neuronophagia is not a frequent finding

4 Foci of hemorrhage are found around the smaller vessels, particularly near the sylvian aqueduct Many vessels contain large numbers of polynuclears, almost constituting a thrombus Less frequently hemorrhages may be found in the cerebral substance

5 Parenchymatous infiltrations with lymphocytes, polymorphs, plasma cells, and other cellular elements are to be found

6 Marinesco (1918 *a*) recorded the presence of corpuscles staining by Gram and Leishman about 1 μ in diameter, either isolated or in pairs, in the perivascular

Blood The reports of blood examination seem all to refer to cases of later date, but they are included here for convenience As a general rule the white blood count has been found normal, but on occasions a neutrophil leukocytosis up to 20,000 per c.mm. has been recorded, and the more acute the case the greater this leukocytosis (Berger and Untersteiner, 1925). It has been said that the presence of eosinophilia, even up to 50 per cent, is a sign of good prognostic significance (Bohrod *et al*, 1931).

Duration of Illness

The average length of illness in patients who recovered was as follows (Parsons, MacNalty, and Perdrau): age up to 10, 4 to 7 weeks; age 10 to 15, 11 to 12 weeks, age 15 to 30, 5 to 8 weeks, over 30, 8 to 10 weeks.

In cases with a fatal result the same authors stated that 50 per cent. died within 2 weeks and 80 per cent within 4 weeks.

Sequelae

These were recorded by a number of authors, particularly MacNalty (1918) and Parsons, MacNalty, and Perdrau, the following being commonly observed failure of the general health, disorders of the mind, salivation; tremors, monotonous speech, ocular defects, pareses of face and limbs, athetosis, parkinsonism, with facial mask, neck bent forward, hypertonic and tremulous arms, and festinant gait In the Sheffield outbreak of 1924 there was a definitely increased liability to parkinsonism in males (Hall and Yates, 1926) Parkinsonian cases were probably infectious, although cases of contact infection were only rarely recorded (e g, by Crouzon and Horowitz, 1929, Netter, 1933).

Mortality

The case mortality rate for 1,273 cases notified during 1919 and 1920 was 48 3 per cent (Parsons, MacNalty, and Perdrau, 1922). There was no appreciable difference in regard to the sexes. With regard to age, in infants (0–1 year) the percentage dying was high (75 per cent), but this percentage decreased to 33 per cent for the age group 10 to 15 years Thereafter the percentage rose steadily to attain 80 per cent in the age group 70–80 The authors quoted regarded the high case mortality rate as fallacious, owing to the number of mild and abortive cases either missed or not certified as encephalitis lethargica. They gave the case mortality rates from numerous other countries, of which may be mentioned the United States (1918–19) 34 per cent, France (1919–21) 37 per cent, and by contrast, South Africa (native patients, 1920) 92 per cent.

CLINICAL FEATURES OF THE LATER CASES (1920 TO 1924)

In 1920 the disease altered in its characteristics in various directions, thus (*a*) pyrexia was slight, (*b*) ocular manifestations were slight, (*c*) lethargy gave place to excitement (Bramwell, 1921)

In 1923 a representative outbreak in Liverpool was studied by Stallybrass Of 130 cases 45 per cent were oculolethargic, 14 per cent myoclonic, 25 per cent. choreiform, and 16 per cent psychomotor Evidences of motor excitement were thus somewhat commoner than lethargy and ocular palsies, and sleeplessness, hypermotility, twitchings, grimacings, tachypnea, and occupational delirium were all found. Parkinsonism was a common sequel The case mortality rate was 40 per cent

A similar outbreak in Sheffield in 1924 was recorded by Hall and Yates (1926)

CLINICAL FEATURES AT THE PRESENT DAY

At the present day sporadic cases of encephalitis lethargica are seen from time to time. The commonest type is comparatively mild, and ambulant cases are met with Sometimes only the onset of parkinsonism shows the true nature of some

mononuclears Hemorrhages occur in the pia arachnoid over the hemispheres, brain stem, and cord, and there are usually collections of mononuclear phagocytic cells around the hemorrhage. Vascular siderosis is usually present in the anterior half of the globus pallidus.

Changes are widespread and the substantia nigra, nuclei of the brain stem, and the basal ganglia all show varying degrees of involvement. The following areas are involved in almost every case. red nucleus, globus pallidus, substantia nigra, dentate nucleus, and olives. The primary change is a cell destruction which is followed by growth of the astrocytes. This cell destruction is progressive and indicates the continued activity of the causal agent. The destruction is patchy and different cell masses are affected more or less independently, thus, one nucleus may be severely involved while a neighbor is unaffected The process differs from that observed in the acute stage, in that cell destruction and reparative gliosis are features, rather than activity of the cellular elements derived from the blood and vessels The change is a simple one and specific only as regards the site of involvement.

C. Pathology of the Remainder of the Body

Boyd (1920 *a*, *b*) described vascular and degenerative changes in the kidneys, and, rarely, widespread hemorrhages in the serous membranes. Netter (see Netter, Cesari, and Durand, 1921 *a*, *b*) attached great importance to round cell infiltrations of the salivary and parotid glands Apart from these lesions the remainder of the organs is usually found to be healthy.

EPIDEMIOLOGY

The information contained in this section has been summarized from the extensive work of the following investigators, mainly during the years 1918 to 1926 when the disease assumed epidemic proportions· James (1918 *a*, *b*), MacNalty (1919, 1919–20, see also 1937), Bernard and Renault (1920), Netter (1920 *c*, see also 1933), Kling and Liljenquist (1921); Smith (1921), Parsons, MacNalty, and Perdrau (1922), Wynne (1926) The statistical aspect of the disease has been dealt with by Stocks (1932).

Topographical Distribution

The distribution of cases followed closely that of the population, and therefore the majority of cases was urban rather than rural. No part of the country was particularly affected, and in individual towns there was no significant grouping of cases in tenements, streets, or particular localities

Possible Association with Influenza

On account of the pandemic of influenza more or less coexistent with that of encephalitis lethargica, it was only natural that some association between the two conditions should be sought Two main views were advanced, first, that influenza rendered the individual susceptible to encephalitis, and secondly, that encephalitis was an influenzal manifestation Without entering into the subject in detail (see Parsons, MacNalty, and Perdrau, 1922, for a longer discussion of the subject, also Jordan, 1927) it is sufficient to say that the balance of opinion was in favor of the unlikelihood of both views Influenza did not predispose to encephalitis and encephalitis was certainly not a nervous form of influenza More recently, however, it has been reported that influenza virus may occasionally cause an encephalitic illness (Brown *et al*, 1945).

Age, Sex, and Social Conditions

While the disease occurred from infancy to advanced old age, it was found chiefly in those approaching adult life (i e., up to 20 to 30), and thereafter there was a diminished liability to infection.

region. He suggested that these structures were protozoa. Levaditi and Harvier (1920 *e*) described corpuscles 4 to 5 μ in diameter in perivascular spaces, composed of a central chromatin mass and a blue cytoplasm.

7. Boyd (1920 *b*) pointed out that in a number of cases where there was cranial nerve disturbance, the corresponding nerve fibers were found to be pressed upon by dilated vessels, the nuclei being healthy.

8 Focal edema in the brain stem and basal ganglia may occur.

9. Proliferation of the lining cells of the aqueduct of Sylvius has been described The cavity becomes partly occluded by filiform digitations observable symmetrically at the posterior angles (Ravairt, Nayrac, and Dubois, 1929).

10. The pia mater shows considerable vascular dilatation, and hemorrhages are also found.

11. Attempts have been made to account for the lethargy on the basis of specific pathological lesions, but no satisfactory results have been achieved. It is probably not dependent on increased intracranial pressure (Bramwell and Miller, 1920), and may be due to interruption of the afferent stimuli passing to the thalamus.

12. The most important inclusion bodies are those known as the "minute bodies" of Da Fano (Da Fano and Ingleby, 1919, Da Fano, 1921 *a*, *b*, *c*, Shaw, 1921; Hume, Nattrass, and Shaw, 1922; and many others) The bodies occur in the cytoplasm of the nerve cells, stain black by Bielchowsky's silver stain, and are best demonstrated by toluidine blue or polychrome methylene blue. In the unstained state they appear yellowish-brown, do not give the test for masked iron or sulfur, are insoluble in acids and alkalies, and do not stain with Sudan or Scharlach Usually each body (or pair of bodies) is surrounded by a halo and measures 0.4 μ in diameter. The cells containing these bodies rapidly degenerate Bodies may also be found extracellularly Similar bodies have been found in the salivary glands. Da Fano bodies of precisely similar type occur in experimental herpetic encephalitis of animals. The bodies have not been sufficiently studied for a definite opinion as to their nature to be expressed, but they may well represent aggregates of the causal virus agent.

Dawson (1933, 1934) described eosinophilic intranuclear bodies which were found either with or without intracytoplasmic bodies The intranuclear bodies were round or oval and varied from twice the size of the nucleolus almost to that of the nucleus itself The intracytoplasmic bodies occurred as small pink masses or larger irregular structures The bodies were found in the motor cortex, red and caudate nuclei The intranuclear bodies would appear to be of the Lipschutz type and similar to those found in herpes

The majority of observers holds the histological picture to be specific, and yet at the same time to be somewhat similar to that of encephalitis due to African trypanosomiasis On the strength of this similarity Bassoe and Hassin (1919) suggested that a protozoon was the cause of encephalitis lethargica, but this opinion has never been seriously entertained

B. Chronic Infections

Microscopically, as the disease progresses to chronicity, alterations in the nerve cells are accentuated, while the perivascular reaction largely subsides The histological picture has been described by various authors (see, e g, Levaditi and Harvier, 1920 *e*, Reynolds and Slater, 1929–30, Carmichael, 1930–1). Neustaedter and Liber [illegible] of their own The following

destruction of the large multipolar cells in the substantia nigra A purely reparative *proliferation* of the astrocytes occurs as a late part of the picture. The blood vessels, especially in the substantia nigra, show well marked perivascular infiltration with

have both been advocated. In all probability none of these measures exerts more than a temporary and slight effect on the course of the disease. Successful results have been reported, (a) after injections of the sera of rabbits hyperimmunized against herpes, (b) after immunization against a neurotropic herpes strain, and (c) after injection of a *formolized* virus vaccine (Neal and Bentley, 1932, Neal, 1934).

THE ETIOLOGY OF ENCEPHALITIS LETHARGICA

Encephalitis lethargica presents many of the characteristic features of an infective disease, thus, the pathological picture is typically infective, and cases of contact infection have been recorded on a number of occasions. The causal agent is, however, as yet unidentified.

The main theories that have been advanced are that encephalitis is caused by (1) a toxicosis, (2) a cultivable bacterium, (3) a virus other than that of herpes, (4) the virus of herpes.

1. The Rôle of Toxicosis

Veillard (1929) suggested that the disease is essentially a toxemic condition from the alimentary tract. Beans, corn, and other substances were alleged to be acted on by bacteria and in this way an encephalitogenic agent was produced.

A number of authors suggested that the encephalitogenic "toxin" might be produced from organisms growing elsewhere in the body, i.e., in the nasopharynx (Martin, 1918) or the gallbladder (Salzman, 1924, 1925).

Finally, various alleged deficiences in the liver, or sugar or nitrogen metabolism have been blamed (e.g., by Meyer-Bisch and Stern, 1923, Buscamo, 1924, Runge and Hagemann, 1924–5).

These theories are, in our opinion, totally inadequate to explain the various features of encephalitis lethargica, particularly its frequent occurrence in epidemics.

2. Cultivable Micro-organisms as the Causal Agents

von Wiesner (1917) injected a monkey subdurally with brain emulsion from a fatal case of von Economo's. The animal died 46 hours after the injection, having been somnolent and partially paralyzed. A gram-positive diplococcus was isolated.

Strauss, Hirshfeld, and Loewe (1919) isolated a filtrable agent from cases of encephalitis which produced lesions in a monkey resembling epidemic encephalitis. Loewe, Hirshfeld, and Strauss (1919) carried out further experiments by injecting suspensions of nasopharyngeal mucosa into rabbits and monkeys. Some of the latter developed lethargy, fever, and ptosis, while histologically the rabbits' brains showed lesions similar to those of man.

Loewe and Strauss (1919, 1920) obtained growths of small globoid bodies in Noguchi's spirochete *medium* from the brains of inoculated animals and from human cerebrospinal fluid. Numerous other workers isolated organisms cultivable in ascitic fluid or other rich media from cases of encephalitis, usually from the nasopharyngeal washings, and less often from the cerebrospinal fluid, blood, or brain (e.g., Bastai, 1920, 1921 *a*, *b*, Ottolenghi, d'Antona, and Tonietti, 1920, Maggiore and Sindoni, 1921, Thalhimer, 1921, 1922, Rosenow, 1924, Evans and Freeman, 1926, and numerous others described in the Matheson Survey, 1929). McCartney (1924) was not, however, able to isolate any globoid bodies from cases of encephalitis, and suggested that the various organisms described were accidental contaminants.

There have been many fallacies in the above reports, which are not generally accepted. Many were undoubtedly working with contaminants which either gained access during the postmortem in the case of brain, or else were present in the naso-

The general consensus of opinion indicated that the sexes were equally affected Social conditions such as *overcrowding, insanitary environment, social status,* and occupation played no part in determining the incidence of the infection

The Method of Spread

Routine epidemiological investigations of the possible rôle of food, milk, water, insect vectors, and fomites yielded completely negative results All observers agreed on the rarity of case-to-case infection, and the epidemic was essentially composed of a large number of sporadic cases. Thus, Smith (1921) detected no case of infection amongst 900 contacts in the United States, and in France, Bernard and Renault (1920) found no evidence of direct contagion resulting from any one of 400 cases

A number of well-authenticated cases of contact infection has, however, been recorded, thus, MacNalty (1919–20) investigated an outbreak in a girls' home in Derby (England) where 12 cases occurred among 22 inmates. He suggested that the infection had arisen from a carrier or mild abortive case. Zinsser (1928) also recorded an institutional outbreak. Cases of infection in families and other contacts have also been recorded on occasions (MacNalty, 1919, Netter, 1920 *c*, see also 1933, Kling and Liljenquist, 1921, Stallybrass, 1923, Wynne, 1926, Crouzon and Horowitz, 1929).

Netter stressed the part played by the saliva in the spread of contagion, but this was not generally accepted as an adequate explanation.

It is difficult to see how the virus spread from case to case unless it were by the air Indeed, were it not for the well-authenticated cases of contact infection the very infectivity of encephalitis lethargica might have been questioned on purely epidemiological grounds. Suspicion was naturally directed toward the part played in the spread of infection by carriers, mild, abortive, or parkinsonian cases, but even these would not account for the majority of instances of the disease.

If the method whereby the virus spread from case to case was obscure, still more so was the route whereby it actually reached the central nervous system. *Probably the portal of entry was the respiratory tract, but whether the virus* reached the brain via the blood stream or via the olfactory nerves and their perineural spaces was not known An interesting observation tending to support the party played by the nasal mucosa was made by Bramwell (1921). A patient had suffered from a nasal discharge due to a polypus for some considerable time Eventually the obstructing tumor was removed, presumably severely traumatizing the nasal mucosa, and a few days later a typical encephalitis lethargica developed

Numerous cases of transmission of the disease by an encephalitic mother to her newborn baby were recorded (Harris, 1918, MacNalty, 1919, Sousa, 1920, Parsons, MacNalty, and Perdrau, 1922) Usually the child developed somnolence, myoclonus, retention of urine, or other symptoms shortly after birth, but eventually recovered

Prevention

As the disease is manifestly of such low infectivity it is questionable whether elaborate precautions need be taken to isolate the patient, or *quarantine contacts*, but in actual practice the patient is usually isolated in hospital and children kept from school for some weeks (see *Memorandum*, 1927)

TREATMENT

Convalescent serum has been used by certain workers, but evidences of beneficial effect would appear to be only slight (Grunewald, 1920, Brock, 1931, Lapage, 1933) Convalescent cerebrospinal fluid has been injected subcutaneously (Collitino and Vegni, 1920) Intraspinal injection of the patient's own serum (Brill, 1920), and subcutaneous injection of the patient's own blood (Bourges and Marcandier, 1920)

any less valid on this account, and suggested that the control animal had become spontaneously infected with the virus of encephalitis lethargica. McIntosh's results have not received general confirmation and meanwhile must be accepted with some reserve

Later, McIntosh (1923) suggested that rabbits might be used for diagnosis. He injected saline suspensions of basal ganglia and cerebrospinal fluid intracerebrally. Positive results consisted in the development of symptoms 48 hours later with death in 5 to 6 days. Histologically, the lesions were said to be typical of encephalitis. Such results were achieved with 3 out of 5 brain emulsions, and 1 out of 4 cerebrospinal fluids tested A further paper was published in 1927, and with Scarff in 1928

These results are not easy to interpret, and are contrary to the great bulk of experimental work detailed elsewhere in this chapter, in which a virus pathogenic for the rabbit was isolated only with extreme rarity, or by a special technique

(c) *Miscellaneous results.* A large number of workers (see Matheson Surveys, 1929, 1932) has reported the production in animals of keratitis, encephalitis, or other lesions with material from cases of encephalitis. This material usually proved sterile on ordinary media and had often been filtered The experiments were usually very inconclusive, however, and no well-recognized strain of virus emerged The effects noted were probably in the main nonspecific, or else due to an unrecognized bacterial contaminant or to spontaneous encephalitis Probably in some cases a weakly virulent strain of herpes virus was actually present It has even been suggested that the mumps virus is the cause of encephalitis lethargica, but this has not received any serious consideration (Gundersen, 1927)

4. The Herpes Febrilis Virus

There is no doubt that herpes is capable of causing a fatal encephalitis in man, inclusions can be found readily in the nuclei of the brain cells, and virus can be isolated (see Ch. XVII). In general, however, herpetic encephalitis, as at present observed, appears not to resemble encephalitis lethargica very closely.

(A) ISOLATION OF HERPES VIRUS FROM CASES OF ENCEPHALITIS LETHARGICA

A number of strains of virus has been isolated from cases of encephalitis lethargica since the first report by Levaditi and Harvier (1920 *a*). In almost all these cases the virus has been carefully studied by cross immunity and other experiments, and its identity with herpes febrilis rendered almost certain. (The properties of these strains are described below in section C) It is not clear whether all the strains to be mentioned were isolated from typical cases of lethargic encephalitis Some of the cases may have been more acute, resembling herpetic encephalitis

1 *Levaditi's strains* Levaditi isolated 3 distinct strains of virus and these will be considered in some detail, as much work has been carried out, particularly on one of these strains (C)

(*a*) *Strain* C was isolated from the brain of a case of encephalitis by rabbit injection (Levaditi and Harvier, 1920 *a* and *e*) Unfortunately, however, the patient suffered at the same time from facial herpes (Rouillard, 1921), and as it is well known that the virus may be found in the cerebrospinal fluid in herpetic eruptions (see Ch XVII), it is difficult to attach much importance to the fact of this isolation However, the great bulk of the French work has been carried out on this strain, and on the basis of its undoubted identity with the virus of herpes, Levaditi and his associates have claimed that encephalitis is a herpetic infection. Strain C has been maintained by cerebral passage in rabbits since its original isolation, and definite loss of virulence has occurred Originally strongly kerato- and encephalito-genic, the strain now fails to produce keratitis, and only very rarely causes encephalitis This loss of virulence has been studied by a number of authors and the weak strain used for various experiments, more particularly in connection with "auto-

pharynx quite apart from encephalitis. Certain workers were also unaware of the existence of spontaneous encephalitis of rabbits.

3. The Rôle of Viruses other than Herpes

(*a*) *Work of Kling, Davide, and Liljenquist* (1922 *a–f*). These Swedish workers reported the isolation of a strain of virus from cases of encephalitis lethargica which showed no cross immunity reactions with herpes febrilis. It did not produce keratitis on corneal inoculation, but the rabbits died some weeks later from encephalitis It was heat resistant. Although interest was aroused at the time, this soon lapsed when Levaditi, Nicolau, and Schoen (1924) showed that the "virus" was only that of spontaneous encephalitis (*E. cuniculi*), from which infection Kling's rabbits were evidently suffering. However, as Doerr and Zdansky (see below) were able to isolate herpes virus from material sent by Kling, it is probable that he may actually have been

(*b*) *Work* … McIntosh (1918), McIntosh and … om the Derby institution outbre … ycerol for 14 days was used for inoculation, but it was said to be very soft and decomposed One rhesus monkey was injected with unfiltered brain material intracranially and intraperitoneally. After about 14 days it became drowsy and weak, and died 7 days later Postmortem, tuberculosis of the lungs was found, and examination of the brain showed only a few small hemorrhages in the midbrain. A *Cercopithecus patas* monkey was similarly injected with a Berkefeld filtrate. After 7 days it developed an excited fit but recovered the next day. Six weeks after the injection, it had a severe fit and remained rigid and tremulous and disinclined for food until death almost 2 months after injection.

Microscopically, the central nervous system showed active inflammatory change in the posterior half of the left basal ganglia and junction of left basal ganglia and midbrain. Slight perivascular infiltration in the cerebral pia was also noted The right globus pallidus showed engorgement, hyaline thrombosis, and perivascular hemorrhages. There was evidence of *ante mortem* neuronal degeneration in the anterior horn of the lumbar cord, cerebrum, and elsewhere.

McIntosh (1920) continued his previous experiments by injecting 2 cynomolgus monkeys intracerebrally and intraperitoneally with the brain of the previous patas monkey One cynomolgus monkey remained quite healthy The other remained well for about 3½ months, when muscular tremors were noted Ten days later the animal became somnolent, and in another 2 weeks the hind legs were weak. One month after the first appearance of symptoms it became very excited and had an epileptiform fit. Finally, 5 months after injection it became so weak that it was killed

Microscopically, acute inflammatory changes were observed in the brain, mainly in the basal ganglia Glial proliferation, perivascular infiltrations with lymphocytes, congestion, perivascular hemorrhages, and degenerative changes in the ganglion cells were all noted

The brain was passaged to a baboon, but it died after 4½ months without microscopic evidence of encephalitis

Rabbits were injected intracerebrally with monkey brain, one developed encephalitic symptoms and was killed in 8 days Histologically, its brain showed some lymphocytic infiltration in the meninges and perivascular sheaths

A cynomolgus monkey used as a control developed symptoms precisely similar to the one injected Histologically, its brain showed lesions in the basal ganglia typical of encephalitis lethargica.

According to the usual manner of interpreting animal experiments, the occurrence of this spontaneous encephalitis in the control would have seriously lowered the value of McIntosh's results. He did not, however, think that his results were

sterilizable neuro-infections (Levaditi); (2) the effect of glycerol in "unmasking" the virus, and the action of "aggressins" (Perdrau).

1. The theory of autosterilizable neuro-infections.

This theory has been largely propounded by Levaditi and his colleagues L dit and Nicolau (1924) showed that cynomolgus monkeys injected with v isolated from encephalitis contracted an encephalomyelitis, histologically typ yet apparently the brain was avirulent for rabbits This observation led Leva Sanchis-Bayarri, and Schoen (1928) to introduce the term "autosterilizable ne infections" to cover those cases where virus could not be isolated, althoug presence was anticipated These workers suggested that the virus primarily tacked and destroyed nerve cells, and that the body then reacted to defend it This reaction, shown by cellular infiltrations, neuronophagia, and gliosis, m result in the death of the virus But in brain where so much of the tissue is to life this reaction produced a fatal result, with consequent failure to isolate living virus. It would appear that most of these negative results were found in case of animals which had died after 3 or more weeks' illness, in which the v had been killed by the cellular reaction, the extent of this reaction making the tinuance of life impossible Further, the strain of virus used to inoculate such mals has usually been of low virulence (strain C) Similar conclusions have arrived at by later workers (Lépine, 1928, Levaditi, 1929, Lépine and Schoen, 19

It is questionable, however, whether the absence of the virus from such b is not merely apparent, for Lépine (1930), by cataphoresis, has separated off a virus from brains apparently inactive on intracerebral injection Also, it is prob that, although a brain may appear avirulent at first, after serial passage it yield virus.

At any rate, as many of the human cases examined have been acute in nat it is unlikely that this mechanism could wholly account for the total failure o many workers to isolate the virus

2. Effect of glycerol.

It has been shown that virus isolated from brains of cases of encephalitis is n active after treatment in glycerol than before (Levaditi, 1922, Berger, 1923, drau, 1925 *b*). Similar observations have been made with herpes virus isolated f herpetic vesicles (see Ch XVII)

It appears as if some substance exists in fresh brain which exerts an inhibi effect on the virus, and that glycerol acts by destroying this inhibitory factor many investigators have used fresh human brain or cerebrospinal fluid for t animal inoculations, this fact may undoubtedly explain some of the failures to late a virus.

Perdrau (1925 *b*) attempted isolation from human brains by stimulating virus therein with "aggressins." This method developed directly out of work herpes virus (1925 *a*, see Ch XVII) in which he found that the brains of her immune rabbits had an "aggressin-like" action when added to virus, on intracere injection of the mixture, the usual incubation period was markedly shorte Perdrau's method consisted in placing the midbrain and basal ganglia in glyc for a week or so and then stimulating the virus supposed to be therein by on three procedures (*a*) By adding the brain of a herpes-immune rabbit (the b having been in glycerol for 2 to 3 weeks) to the human brain and injecting mixture The herpes-immune brain was said to contain aggressins, and by this m Perdrau succeeded in isolating herpes virus from the brain of a case of encephal which proved avirulent in the fresh state (*b*) By producing the aggressin in animal to be injected The human brain was injected intradermally and the foll ing day a further injection (with herpes-immune brain added) given intrac brally, on each of the next 7 days a cutaneous injection was given by deep scarif

sterilizable neuroinfections" (Levaditi, Sanchis-Bayarri, and Reinié, 1927; Levaditi, Sanchis-Bayarri, and Schoen, 1928, Levaditi, Lépine, and Schoen, 1929, Lépine and Schoen, 1930). Olitsky and Long (1928) also studied the virus and succeeded in infecting guinea-pigs.

(*b*) *Strain CH* (Levaditi, Harvier, and Nicolau, 1922). This strain was isolated from the nasopharynx of a case of encephalitis The strain produced keratitis on corneal inoculation, sometimes with the development of encephalitis, and proved to be of the same biological nature as strain C. Again, however, the nasopharynx is known to contain herpes virus in normal persons and so this strain also is suspect.

(*c*) Levaditi and Harvier (1920 *c*) also isolated a third strain from the brain of a choreiform case of encephalitis by intracerebral injection of rabbits This strain was of low virulence, however, and was not maintained, which is unfortunate, as *its claim to consideration would seem to be more definite than strains C or CH*

2. *Netter, Cesari, and Durand* (1921 *a*) isolated a weakly virulent herpes virus from the brain of cases of encephalitis on two occasions.

3. *Basel strains.* By the work of Doerr and his associates, 3 strains were isolated in Basel. Strain 1 was isolated from the cerebrospinal fluid of a case, by intracranial injection of a rabbit, and was extensively studied (Doerr and Schnabel, 1921 *a, b, c*). Strain 2 was isolated from the brain by intracerebral injection of rabbits (Doerr and Berger, 1922). Strain 3 was isolated from the brain (after 14 days in glycerol) by Berger (1923).

4. *The Berlin strain* was isolated by Schnabel (1922) from the cerebrospinal fluid, by intracranial injection of rabbits

5. *The Vienna strain* was isolated from the cerebrospinal fluid, by intravenous injection of rabbits (Lauda, 1923, Luger and Lauda, 1924).

6. *Doerr and Zdansky's (1924) strain* was isolated from brain sent (in glycerol) by Kling, using corneal inoculation of rabbits.

7. *Bessemans and van Boeckel's (1923 a, b) strain.* These workers injected a number of rabbits with brain, cerebrospinal fluid, and nasopharyngeal secretion from cases. From 7 rabbits herpes virus was recovered, but it is uncertain how many cases this represented. At any rate, from a few cases these authors were able to isolate herpes virus

8. *Danila and Stroe* (1923 *a, b*) isolated an encephalitogenic, nonkeratogenic virus from the nasopharynx of a case, but as there was a coexistent herpetic eruption, this result should be interpreted with considerable reserve.

9 *Sicard, Paraf, and Laplane* (1923) isolated a strain (by intracerebral injection of rabbits) from the mesencephalon of a case of parkinsonism

10. *Perdrau's (1925 b) strains.* By means of a technique specially designed to recover herpes virus from the brain (see below) Perdrau recovered 3 strains, one of which (E L. 1) was more extensively studied than the others

11. *Gay and Holden* (1932–3, 1933) isolated herpes virus from the basal ganglia of a case of parkinsonism by injection of rabbits and monkeys They obtained a similar virus from a case of ascending myelitis following a monkey bite, but this case should not be accepted as one of encephalitis lethargica, although Gay and Holden appear to have regarded it as such

12. *Kreis* (1938) isolated herpes virus from the saliva of 3 cases of postencephalitic parkinsonism

(B) EXPLANATIONS TO ACCOUNT FOR FAILURES TO ISOLATE HERPES

Numerous workers (presumably many never published their results) have entirely failed to isolate a virus from cases of encephalitis lethargica (e g, Ford and Amoss, 1924, Dible, 1925, Flexner and Amoss, 1925, Douglas, 1926, Crouzon and Horowitz, 1929, Dawson, 1933, Rupilius and Szekely, 1934) To explain these results, those who have been more fortunate have advanced hypotheses (1) auto-

vier, and Nicolau, 1921 *a, d*, 1922). The virus passed through the placenta and was isolated from the brain of a fetus by Levaditi, Harvier, and Nicolau (1921 *c*).

2. *Guinea-pigs* were susceptible to intracranial injection of rabbit passage virus (Levaditi and Harvier, 1920 *b*, Doerr and Schnabel, 1921 *a, b, c*). Working later, Olitsky and Long (1928) found that strain C could not be transmitted by direct intracerebral injection. They succeeded in transmitting the infection by the following technique The animals were inoculated intracerebrally, and the left cornea was scarified with virus, and on the 3rd day the right cornea also was scarified On the 6th to 7th day the animal developed the typical syndrome of circling, tremors, contractions, urinary retention, and marked salivation The virus was transmitted by passage, and after 3 passages it was merely necessary to inject the material intracerebrally, the additional scarification becoming unnecessary.

3. *Mice* were found to be susceptible to rabbit passage virus on intracerebral, intraperitoneal, and subcutaneous injection (Levaditi and Harvier, 1921 *a*, Doerr and Schnabel, 1921 *a, b, c*, Levaditi, Harvier, and Nicolau, 1922).

4. *Monkeys*. It was found (Levaditi and Nicolau, 1924) that intracranial injection of certain monkeys and chimpanzees caused the development of an encephalitis, acute or chronic, and histologically typical.

Morphology and filtrability of the virus.

Inclusion bodies. The *neurocorpuscules encephalitiques* (Levaditi, Harvier, and Nicolau, 1921 *a*, 1922) occurred in the nuclei (rarely in the cytoplasm) of nerve cells in the hippocampus of infected rabbits. They measured 1 μ in diameter and were surrounded by a clear halo. Schnabel (1924) reported that typical Lipschütz bodies developed in the epithelial cells of the infected rabbit cornea

The virus passed through a Chamberland L_1 and L_3 (Levaditi and Harvier, 1920 *a, e*, Levaditi, Harvier, and Nicolau, 1921 *b*).

Culture.

It was shown that the virus conserved its virulence at 37° C in tissue culture as long as the cells were still viable (Levaditi and Harvier, 1920 *e*), but more extensive experiments on actual propagation in tissue culture do not appear to have been carried out

Reaction to physical and chemical agents.

The virus was destroyed at 55° C. in half an hour

After desiccation *in vacuo* the virus conserved its virulence for at least 44 days, but if desiccated over sulfuric acid, for not much longer than 4 days (Levaditi, Harvier, and Nicolau, 1922)

Various chemical substances given to rabbits increased the virulence of virus subsequently injected, such as chloral, chloroform, and ether (Levaditi, Harvier, and Nicolau, 1922), alcohol and thyroxin (Levaditi, Lépine, and Schoen, 1930) Raising the animal's temperature achieved the same result (Levaditi, Lépine, and Schoen, 1929)

The virus was, of course, glycerol-resistant and this effect has already been discussed in detail The virus did not readily diffuse out of a piece of brain placed in glycerol (Levaditi, Harvier, and Nicolau, 1921 *a*)

The virus was adsorbed by animal charcoal and kaolin (Levaditi and Nicolau, 1923 *a*) and was susceptible to bile (Levaditi and Harvier, 1921 *b*, Levaditi, Harvier, and Nicolau, 1922)

The virus survived in the tissues of infected animal cadavers for at least 48 hours (Levaditi and Harvier, 1920 *e*)

The virus conserved its activity at room temperature for at least 50 days in water and 86 in milk (Levaditi, Harvier, and Nicolau, 1922, Levaditi and Harvier, 1921 *a*)

tion (the scrapings of each previous scarification being used for the next in series) By this means Perdrau isolated herpes from another case (*c*) Finally virus was isolated in a third case by repeated intradermal passage of human brain material in rabbits.

(C) PROPERTIES OF HERPES VIRUS ISOLATED FROM CASES OF ENCEPHALITIS LETHARGICA

Human experiments.

Schnabel (1923) inoculated himself on the skin with rabbit brain material (Berlin strain) with the production of only a slight reaction. Bastai and Busacca (1924, 1925) injected the same virus into the subarachnoid space of one patient with negative results, and into the skin of three others with only a slight reaction

Strain C was injected intrathecally (Nicolau and Poincloux, 1924–5), but could not be recovered by animal experiment even 8 hours later. It is evident, therefore, that these experiments do not strengthen the position of herpes virus as the cause of encephalitis lethargica.

Animal experiments.

1. *Rabbits.* (*a*) *Corneal injection* (Levaditi and Harvier, 1921 *a*, Levaditi, Harvier, and Nicolau, 1921 *a*, 1922, Doerr and Schnabel, 1921 *a*, *b*, *c*; and many others). Keratoconjunctivitis was found to develop 24 to 48 hours after corneal scarification, and, in the case of a virulent strain, spread occurred to the brain (within 48 hours) via the optic and trigeminal nerves. The animal died with the typical encephalitic syndrome in 6 to 8 days after inoculation.

(*b*) *Intracranial injection* (Levaditi and Harvier, 1920 *a*, *e*, Doerr and Schnabel, 1921 *a*, Levaditi, Harvier, and Nicolau, 1921 *a*, 1922, Schnabel, 1922, Luger and Lauda, 1924, Perdrau, 1925 *a*, *b*). Following injection of human material there was usually an incubation period of some 8 days before symptoms developed, but in the case of rabbit passage virus this was shortened to 4 to 6 days. The symptoms were typical of herpetic encephalitis, tremors, fits, and somnolence all occurring

Histologically, brains of animals dead of encephalitis showed lesions which were widespread, though most marked in the hippocampus. There was much destruction of nerve cells with tigrolysis, neuronophagia, and infiltration with polymorphs Miliary abscesses might even be found, and the acuter the inflammation the greater the number of polymorphs present In cases where death had been more delayed the main cellular infiltration was mononuclear. The meninges showed infiltration with lymphocytes, macrophages, and plasma cells, hemorrhages were also found Perivascular cuffing with mononuclears and polymorphs was also observed in the earlier stages.

(*c*) *Cutaneous injection* (Levaditi, Harvier, and Nicolau, 1921 *f*, 1922). A papulosquamous eruption followed cutaneous injection, and the animal died from encephalitis Paresis of the hind limbs might be observed

(*d*) *Other routes of injection.* The rabbit could be infected by the following routes nasal (after trauma or instillation of croton oil), anterior chamber of eye, peripheral nerves, and testicle (Levaditi and Harvier, 1920 *a*–*e*), intratracheal, intramuscular, intraperitoneal (Levaditi, Harvier, and Nicolau, 1921 *f*, 1922), intravenous (Zdansky, 1923, Luger and Lauda, 1924) The following routes gave negative results intragastric, via the salivary gland, and subcutaneous (Levaditi and Harvier, 1920 *e*).

Distribution of virus in the infected rabbit. Examination of an animal dead from infection showed that the virus was present in the brain and spinal cord, but not in the cerebrospinal fluid, blood (yet the polynuclear count might reach 18,000 per c mm.), marrow, internal organs, testicle, salivary glands, spinal ganglia, lymph glands, or nasal mucosa (Levaditi and Harvier, 1920 *c*, *d*, *e*, 1921 *b*, Levaditi, Har-

on *a priori* grounds no virus obtained from the nasopharynx of encephalitic patients can be seriously considered as the etiological agent. The great majority of encephalitis strains of virus has been isolated from the brain, but even here it is possible that the virus might be an accidental invader, and not the etiological agent. Again, the cases described as lethargic encephalitis may have been herpetic encephalitis.

2. *Rarity with which herpes virus has been isolated from encephalitis lethargica.* Only on about 20 occasions has herpes virus been isolated from cases of presumed encephalitis lethargica. The theories brought forward in explanation have already been discussed. The theory of "autosterilizable neuro-infections" rests on no very strong basis of experimental evidence. At any rate, it would not explain the absence of virus from the brains of chronic encephalitics, where the whole pathological process indicates the continued activity of the virus. The demonstration, by Perdrau and others, that glycerol treatment may be needed to unmask a latent virus may certainly explain a number of failures to isolate virus from fresh brain. Yet if herpes virus is the cause of encephalitis lethargica, then it is almost unique in the difficulty with which it can be isolated. In the case of rabies, poliomyelitis, and St. Louis encephalitis, no difficulty is experienced in isolating by animal injection the characteristic causal agent. Moreover, in herpetic eruptions the virus is readily obtainable and no theories have had to be adduced to explain failures. The results of attempts to isolate herpes virus by animal experiments must, therefore, be regarded as very unsatisfactory.

3. *Clinical observations.* Although herpes virus can cause a severe involvement of the central nervous system (see Ch. XVII), such cases do not resemble encephalitis, and this is hardly to be expected if the same agent is responsible for the two conditions.

4. *Pathological observations.* Undoubtedly pathological observations do much to support herpes virus as the etiological agent of encephalitis. There is considerable similarity between the pathological picture of acute encephalitis in the human being (see above) and that observed in the rabbit injected intracranially with herpes virus. The main tissue changes are of the same order, and the "minute bodies" or inclusions of Da Fano are found in both (see Da Fano, 1923). Intranuclear inclusions occur in herpetic encephalitis and have been described in lethargic encephalitis. There is, however, even more histological similarity between human brains and those of partially immunized rabbits suffering from herpetic encephalitis (Perdrau, 1925 *a*). Herpetic infection of monkeys also resembles human encephalitis very markedly both clinically and histologically.

It is evident, therefore, that herpes is able to produce experimentally in animals lesions of a type almost identical with those of human encephalitis lethargica.

5. *Suggested methods of transmission of the virus of epidemic encephalitis.* It has been shown that herpes strains isolated from cases of encephalitis can survive for weeks in milk or water. Epidemiological investigations have definitely shown, however, that the disease is not so spread.

On the basis of animal experiment it has been suggested that the herpes virus may be spread by sexual intercourse. A local lesion results and encephalitis follows (Levaditi and Nicolau, 1923 *b*).

Simmons, Kelser, and Cornell (1933, 1934) suggested that the virus might be spread case to case by means of *Aedes aegypti*, but again epidemiological investigations have failed to incriminate any insect vector.

Levaditi and Netter both stress the importance of the saliva in the spread of infection. While Netter believes that infection may result from contact with an infected person through the medium of the saliva, Levaditi stresses more the rôle of endogenous factors.

Levaditi has stated that 80 per cent. of persons carry a keratogenic salivary virus and 15 per cent. an encephalitogenic virus, both being typical strains of herpes

Immunity.

The most important work was directed toward proving the identity by cross immunity experiments of virus strains isolated respectively from encephalitis and known herpetic vesicles. A typical experiment which proved this identity was that of Doerr and Schnabel (*1921 c*), who found that herpes-immune rabbits resisted corneal and intracranial injection with encephalitis strains. Conversely, they found that animals recovered from a corneal infection with encephalitis strains were locally and generally immune to infection with herpes virus. Levaditi carried out similar experiments and was led to the same conclusions as regards the identity of the two types of strain (see Levaditi, Harvier, and Nicolau, *1922*).

Attempts were made to immunize rabbits actively by injections of encephalitis strains (Levaditi and Harvier, *1920 e*), and it was found that subcutaneous injections of fresh, etherized, or desiccated virus produced partial immunity as tested by the nasal or intra-ocular routes. It was not possible, apparently, to immunize sufficiently adequately to prevent encephalitis developing when the test injection was given intracerebrally. Guinea-pigs were immunized by repeated intraperitoneal injections of virus (Olitsky and Long, *1928*). It was impossible to demonstrate virucidal antibodies in actively immunized rabbits, although the sera of immunized sheep showed complement fixation with rabbit brain antigen (Levaditi, Harvier, and Nicolau, *1922*).

A number of workers has tested the virucidal properties of the serum of acute, chronic, and convalescent cases of encephalitis lethargica for encephalitis strains of herpes, with poor or negative results. Thus, Levaditi and Harvier (*1920 c*) found these antibodies present in the sera of only *1* out of *6* convalescents. Further, the neutralizing power was only apparent when the virus-serum mixture was injected corneally and not intracerebrally (Levaditi and Harvier, *1920 b*, Levaditi, Harvier, and Nicolau, *1921 a*). Blanc, Tsiminakis, and Caminopetros (*1921*) did not find any antibodies in the sera of convalescents of one year's standing.

It should be recalled that Andrewes and Carmichael (*1930*) and others (see Ch. XVII) have shown that the sera of about 75 per cent of normal persons have virucidal properties for known herpetic strains. Gay and Holden (*1931*), working in the same connection, showed that these properties were absent from the sera of cases of encephalitis, this confirmed the work just recorded in which workers failed to find any substantial evidence of virus neutralizing powers for encephalitis strains in the sera of convalescents.

It is claimed that herpetic eruptions are extremely rare in encephalitis lethargica (Netter, *1921 b*). This would scarcely seem to indicate an immune state, however, for it was found perfectly possible to produce herpetic vesicles in encephalitics by scarification of the arm and application of herpes virus thereto (Teissier, Gastinel, and Reilly, *1923*).

(D) A SUMMARY OF THE PRESENT POSITION

As will have become evident from consideration of the various properties of the strains isolated from cases of encephalitis, there is no doubt that they are true strains of herpes virus, as was first suggested by Blanc (*1921*). Accordingly, Levaditi and his coworkers claim that herpes virus causes encephalitis lethargica. Although this theory has never been accepted wholeheartedly outside France and Belgium, other workers in Britain (Da Fano, *1923*, *1924*, Perdrau, *1925 a*), in Switzerland (Doerr and his associates), and in the United States (Gay and Holden, *1932–3*, *1933*), have expressed opinions in its favor. Levaditi's theory will be critically examined in the following paragraphs.

1. Distribution of herpes virus in man (see Ch. XVII). The herpes virus is known to have a wide distribution, even in normal persons, for its presence has been recorded in the cerebrospinal fluid, saliva, and conjunctival secretion. Therefore,

on *a priori* grounds no virus obtained from the nasopharynx of encephalitic patients can be seriously considered as the etiological agent The great majority of encephalitis strains of virus has been isolated from the brain, but even here it is possible that

[illegible]

Only on about 20 occasions has herpes virus been isolated from cases of presumed encephalitis lethargica The theories brought forward in explanation have already been discussed. The theory of "autosterilizable neuro-infections" rests on no very strong basis of experimental evidence At any rate, it would not explain the absence of virus from the brains of chronic encephalitics, where the whole pathological process indicates the continued activity of the virus The demonstration, by Perdrau and others, that glycerol treatment may be needed to unmask a latent virus may certainly explain a number of failures to isolate virus from fresh brain. Yet if herpes virus is the cause of encephalitis lethargica, then it is almost unique in the difficulty with which it can be isolated In the case of rabies, poliomyelitis, and St Louis encephalitis, no difficulty is experienced in isolating by animal injection the characteristic causal agent. Moreover, in herpetic eruptions the virus is readily obtainable and no theories have had to be adduced to explain failures. The results of attempts to isolate herpes virus by animal experiments must, therefore, be regarded as very unsatisfactory

3 *Clinical observations* Although herpes virus can cause a severe involvement of the central nervous system (see Ch XVII), such cases do not resemble encephalitis, and this is hardly to be expected if the same agent is responsible for the two conditions

4 *Pathological observations* Undoubtedly pathological observations do much to support herpes virus as the etiological agent of encephalitis There is considerable similarity between the pathological picture of acute encephalitis in the human being (see above) and that observed in the rabbit injected intracranially with herpes virus The main tissue changes are of the same order, and the "minute bodies" or inclusions of Da Fano are found in both (see Da Fano, 1923). Intranuclear inclusions occur in herpetic encephalitis and have been described in lethargic encephalitis. There is, however, even more histological similarity between human brains and those of partially immunized rabbits suffering from herpetic encephalitis (Perdrau, 1925 *a*) Herpetic infection of monkeys also resembles human encephalitis very markedly both clinically and histologically

It is evident, therefore, that herpes is able to produce experimentally in animals lesions of a type almost identical with those of human encephalitis lethargica

5 *Suggested methods of transmission of the virus of epidemic encephalitis* It has been shown that herpes strains isolated from cases of encephalitis can survive for weeks in milk or water Epidemiological investigations have definitely shown, however, that the disease is not so spread

On the basis of animal experiment it has been suggested that the herpes virus may be spread by sexual intercourse A local lesion results and encephalitis follows (Levaditi and Nicolau, 1923 *b*)

Simmons, Kelser, and Cornell (1933, 1934) suggested that the virus might be spread case to case by means of *Aedes aegypti*, but again epidemiological investigations have failed to incriminate any insect vector

Levaditi and Netter both stress the importance of the saliva in the spread of infection While Netter believes that infection may result from contact with an infected person through the medium of the saliva, Levaditi stresses more the rôle of endogenous factors

Levaditi has stated that 80 per cent of persons carry a keratogenic salivary virus and 15 per cent an encephalitogenic virus, both being typical strains of herpes.

Although these high figures have not been generally accepted, it is agreed that the saliva may on occasions contain herpes virus.

Levaditi's conception (Levaditi, Harvier, and Nicolau, 1921 *e*) of the etiology of encephalitis lethargica is that the virus exists in the saliva in a more or less attenuated form in between epidemics. During epidemics, either on account of a sudden increase in virulence of the virus, or on account of an increased susceptibility of the host, or of both, generalization occurs and encephalitis results. Unfortunately this conception is not based on any considerable amount of experimental work actually referable to man, and we cannot regard it as other than a possible theory

Conclusions.

It has been shown that encephalitis lethargica bears many of the characteristic stamps of a virus infection although no specific virus has yet been generally accepted as the causal agent.

There is no question that the virus of herpes febrilis can cause an encephalitis that resembles encephalitis lethargica in many ways The question that cannot yet be answered is whether herpetic encephalitis and lethargic encephalitis are identical, or whether the etiology of the latter condition awaits discovery. On the whole, the evidence of the last few years has tended to strengthen the view that herpes virus is the cause of lethargic encephalitis, although the position is far from clarified

those of lethargic en-

Epidemiology

The first cases of "St Louis" encephalitis actually occurred in the summer of 1932 in Paris, Illinois (see Leake, Musson, and Chope, 1934). St Louis was not involved till the summer and fall of 1933 (1,100 cases) Then the disease spread to Kansas City and other parts within a radius of approximately 250 miles (Leake, 1933) In 1934 a similar outbreak occurred in Toledo, Ohio (Lowenberg and Zbinden, 1936) Outside this radius, however, serum neutralization tests showed New York to have been affected in 1933 (Webster, Fite, and Clow, 1935). In 1935 a

ST. LOUIS ENCEPHALITIS

In 1933 a remarkable outbreak of encephalitis occurred in St. Louis, and although other cities were visited, the disease has come to be known as St. Louis encephalitis It was realized that the disease was a specific entity unassociated with lethargic or other form of encephalitis then known in America. It closely resembled both in clinical and other respects Japanese (type B) encephalitis, but the viruses were immunologically distinct The outbreak was thoroughly investigated, and fully described in a *Bulletin* of the U.S. Public Health Service (*Report*, 1935).

A virus with characteristic action on monkeys and mice was isolated and has been extensively studied It was not, however, possible to isolate this virus from all cases of apparently typical St. Louis encephalitis (McKinley and Verder, 1933-4) There was a recurrence of the disease in the summer of 1937 (see *J. Amer med Ass*, 1937, Hempelmann, 1938), and since this date the virus has spread widely in the United States It has been studied particularly by Hammon and associates on the West Coast

FEATURES OF 1933 AND 1937 OUTBREAKS

Clinical Features

The symptoms were first described in detail by Leake (1933) and Hempelmann (1934) The features of the 1937 recurrence were similar (see Hempelmann, 1938)

Incubation period This was ascertained accurately in persons entering the infected zone who developed encephalitis within 9 to 21 days of arrival Probably the outside limits were 4 to 21 days

The onset was sudden with headache, high fever, neck rigidity, mental confusion, tremors, and only transient ocular manifestations.

The encephalitic type was characterized mainly by symptoms referable to the central nervous system, and the features were unquestionably those of an encephalitis. The height of the disease was reached in 24 to 48 hours The neck and spine were rigid, Kernig's sign positive, and hyperesthesia was noted, the tendon and plantar reflexes were variable, and the abdominal absent. The pupils were usually small and equal There was considerable mental impairment with some disorientation for time and space Although drowsy and apathetic, certain patients could usually be roused, other patients being sleepless or wildly delirious At the height of the disease, speech was often slurred or aphasia present Fine tremors involving the hands, tongue, and lips sometimes lasted for 2 to 3 weeks

As regards vision, there was sometimes blurring, but severer manifestations such as ptosis were very rare About 25 per cent showed vertigo, ataxia was rarer, and only a few patients showed facial paralysis or spastic monoplegias Involvement of the cord was suggested by the frequency with which retention or incontinence of urine occurred

Fever was usually present, being highest for the first 2 or 3 days (up to 105° F) and falling by lysis to normal in 7 to 10 days, occasionally, however, it might be prolonged irregularly for a month or more

The general infection type showed no specific evidence of involvement of the central nervous system until a few days after the onset. During this period there were symptoms of chills, rigors, neuromuscular pains, headache, photophobia, sore throat, and pyrexia Then the temperature rose, and the characteristic encephalitic picture became manifest.

Mild or abortive cases showed fever, headache, and systemic disturbances, but the nervous manifestations were slight or absent.

After history. Bredeck *et al.* (1938) have recorded a "follow up" study of over 300 sufferers from the original (1933) epidemic. They found that 66 per cent. had completely recovered Only 6 3 per cent. were unable to resume their previous work. They found parkinsonism rare. The usual sequelae were headaches, irritability, some loss of memory, and drowsiness.

Cerebrospinal fluid The fluid was clear and under slightly increased pressure. The cells averaged 50 to 250 per c mm, usually mononuclears, although the earliest counts might show up to 50 per cent. polynuclears The sugar was normal, or slightly increased, and the globulin moderately increased.

The blood occasionally showed a white cell count of 12,000 to 20,000 per c.mm, with a shift to the left of the Schilling count, but these findings were unassociated with the severity of the illness Leukopenia was probably more commonly found

Case fatality. The rate for St. Louis (1933) was 20 per cent., but the rate for the oldest age group was double that of any other group. In the 1937 epidemic, the rate was 23 7 per cent. The Paris rate (1932) was 37 per cent. In fatal cases, death usually occurred after 6 days, and in over 50 per cent within the first 2 weeks.

Pathology

The first full description of the pathological [illegible] McCordock, Collier, and Gray (19[illegible]) [illegible] [illegible]eil, 1934). The changes [illegible]

Brain and [illegible] [illegible]ascular congestion, the cut surface being pin[illegible] [illegible] cases, the gray matter of the entire cortex, midbrain, pons, and cord was so affected In the usual case, however, the congestion was more blotchy, occurring in scattered patches in the cortex, basal nuclei, brain stem, and cord. Petechial hemorrhages might be found in the pia-mater in severe cases.

Microscopically, the following changes were fairly uniformly distributed throughout the central nervous system

1 The meningeal and intracerebral blood vessels were congested, with occasional perivascular hemorrhages Petechiae might be found in the brain parenchyma.
2 Perivascular cuffing with lymphocytes was a regular feature
3 Focal or diffuse infiltrations of microglia, plasma cells, and polynuclears were present Where this was a prominent feature, there was also neuronophagia
4 The extent of degeneration of nerve cells varied with the severity of the infection In mild cases, the changes were of the slightest, but in severe cases there was great shrinking of the cell body, pyknosis, or even complete disappearance No inclusions could be found in nerve cells
5 The meningeal reaction was lymphocytic, never purulent, and was most intense basally.
6 Very rarely small abscesses might be found in the parenchyma

Other organs In one-third of cases there was swelling and congestion of the kidneys with hemorrhagic pyelitis.

It is evident that these pathological features differ from those of lethargic encephalitis, particularly in their more widespread distribution

Epidemiology

The first cases of "St Louis" encephalitis actually occurred in the summer of 1932 in Paris, Illinois (see Leake, Musson, and Chope, 1934) St Louis was not involved till the summer and fall of 1933 (1,100 cases) Then the disease spread to Kansas City and other parts within a radius of approximately 250 miles (Leake, 1933) In 1934 a similar outbreak occurred in Toledo, Ohio (Lowenberg and Zbinden, 1936) Outside this radius, however, serum neutralization tests showed New York to have been affected in 1933 (Webster, Fite, and Clow, 1935). In 1935 a

somewhat similar outbreak occurred in Windber, Pa (Slesinger, 1936). The disease seemed to have disappeared after these outbreaks, as no virus could be isolated from various cases of encephalitis between 1933 and 1937 (McCordock, Smith, and Moore, 1937–8).

In 1937, however, another summer outbreak occurred in St. Louis city and county. Clinically the outbreak resembled the earlier in every respect. Between June 30 and October 18 there were 412 cases (see *J. Amer. med. Ass.*, 1937, Zentay and Basman, 1939). The disease must now be considered as endemic in the United States.

All the outbreaks occurred in the summer and fall, and were strictly limited in duration. Throughout the St. Louis (1933) epidemic, more cases were reported from the suburban than from the city areas, and in the early stages the country rate was 11 times that of the city rate. There was a remarkable freedom from multiple cases in families in all the outbreaks except in Windber, where whole families were involved Once the disease was established, the susceptibility of the individual was more important than exposure to contagion, thus it was often the member of the house least able to move about who was affected

There was no racial, sex, or class predilection, but there was a striking increase in the incidence of the disease with advancing age (Leake, 1933). Thus, 13 per cent of cases occurred in the 25 per cent. of population under 15, 23 per cent. of cases in those from 15 to 34, 29 per cent. of cases in those from 35 to 54, and 35 per cent in those over 55 (only 13 per cent. of the population). In the Windber outbreak, however, only one-tenth of the cases were over 30 years.

It was shown that cases, both in 1933 and 1937, appeared to occur in the vicinity of small streams, in areas characterized by weeds, refuse dumps, open sewage, and ponds, suggesting the rôle of insects (Casey and Brown, 1938, Casey, 1942).

Drinking water and milk were both excluded as sources of infection, and as epidemics occurred in summer, suspicion naturally fell on insect vectors Mosquitoes were considered to be the only likely insects with a range wide enough to explain the distribution of cases. Experiments were carried out with *Aedes aegypti*, *Anopheles quadrimaculatus*, and *Culex pipiens* Although the insects undoubtedly absorbed virus which persisted till their death, they did not infect men, mice, or monkeys by biting (Leake, Musson, and Chope, 1934, Webster, Clow, and Bauer, 1935) The method of spread was not solved, although suspicion rested on insect vectors

On the basis of experimental work, it was tentatively suggested that mice might constitute a reservoir of infection (Harford *et al.*, 1939 *a*, *b*).

In the St. Louis outbreak the health authorities did not insist on quarantine, but isolation was carried out in general (not fever) hospitals (Bredeck and Zentay, 1934)

Rôle of Streptococci

Rosenow has claimed a primary etiological rôle for streptococci (Rosenow, 1933, 1933–4, Rosenow and Jensen, 1933).

FEATURES OF LATER OUTBREAKS

The clinical features of later outbreaks seem similar to those originally described in St. Louis.

It is now recognized that abortive cases may occur Thus Blattner and Heys (1946) isolated virus from the blood of a child suffering from drowsiness, fever, and vomiting St Louis infection must be considered in the differential diagnosis of nonparalytic poliomyelitis and equine encephalitis. Infections due to two of these agents have occurred simultaneously in the one locality.

St. Louis District

From 1939–1944, 12 cases of St. Louis encephalitis were investigated at the Children's Hospital, and it appears that the disease is now endemic in the area (Blattner and Heys, 1945).

California

[illegible] osis being [illegible] ley, 1939, [illegible] must be considered endemic (Howitt, 1942; Hammon, Reeves, and Galindo, 1945). There were 6 cases in 1943, and 3 in 1944 confirmed by isolation of the virus (Hammon and Reeves, 1947). Virus has been isolated from the brain of a fatal case (Lennette, 1946). Most of the cases have occurred in the rural areas of the San Joaquin Valley (especially Kern County).

Antibodies have been found in the sera of animals in the endemic areas, especially horses and birds, such as fowls, antibodies have frequently been found to St. Louis and western equine encephalitis in the one sample; the sera of a few wild rodents have also been found positive (California Mosquito Control Association, 1942, Howitt and van Herick, 1941, 1942, Hammon, Reeves, and Galindo, 1945; Hammon and Reeves, 1947).

There is little doubt that the infection is spread by mosquitoes, and virus has been recovered from *Aedes dorsalis* (Hammon and Reeves, 1945, 1947).

Yakima Valley, Washington

Hammon and his associates made extensive studies on the occurrence of western equine encephalitis and St. Louis encephalitis in man and horses in this valley in the State of Washington, especially from 1939–1942 (see also Ch XCVI). Epidemics occurred each year in July and reached their peak in mid-August; 81 per cent of cases were males, and the case fatality was 22.4 per cent (Hammon, 1941, Hammon and Howitt, 1942)

St Louis infection is endemic in this area, and the sera of many "normal" residents neutralize the virus, the percentage showing antibodies increases with time of residence in the area (Hammon, 1943)

The disease is spread by mosquitoes, and St Louis virus has been isolated from *Culex tarsalis* on 8 occasions, the infection rate being at least 1 210, *Culex pipiens* has also been found infected, there is little doubt that *Culex tarsalis* is the main vector of St Louis and western equine viruses in Yakima (California Mosquito Control Association, 1942, Hammon *et al*, 1942 *b*, *c*, 1945, Hammon and Reeves, 1942, 1945, Reeves and Hammon, 1942) A later report (Hammon and Reeves, 1947) refers to further isolations of virus from *C tarsalis*.

Culex tarsalis has been found to feed on fowls, domestic animals, and man, *Culex pipiens* feeds exclusively on fowls (Reeves and Hammon, 1944). This finding is of importance, and it appears that chickens may constitute an important reservoir of infection, although a much lower percentage of their sera neutralized St Louis than western equine encephalitis virus (Hammon, 1941, Hammon *et al*, 1941 *a*, 1942 *a*, 1945). There is not yet any evidence to incriminate chicken mites in the spread of the virus between chickens in this area (Hammon and Reeves, 1947) The sera of horses and other domestic animals, and a few wild mammals, also neutralized St. Louis virus (California Mosquito Control Association, 1942; Hammon, 1941, Hammon and Howitt, 1942, Hammon *et al*, 1941 *a*, 1942 *a*).

Other Areas in America

Arizona An epidemic occurred in Pinal County among migratory laborers, involving about a dozen people, half being children (Meiklejohn and Hammon, 1942, Hammon, 1943)

Colorado. There was an epidemic of encephalitis in man and horses in 1940 in N. Colorado. Serum samples neutralized the St. Louis virus (Philip, Cox, and Fountain, 1941). Studying the mosquito population in 1943 and 1944, Black, Absher, and McDonald (1945) found *Culex tarsalis, C. pipiens,* and *Mansonia perturbans* to be present.

Minnesota A few cases may have occurred in 1941 (Eklund, 1946).

Oklahoma. Antibodies to the St. Louis virus have been found in the sera of some mammals, but not in chickens (Reeves, Mack, and Hammon, 1947).

Texas. Studies were carried out in Texas in 1942 by Hammon, Reeves, and Irons (1944). Men and horses had probably been infected the year previously with St. Louis (and western equine) virus. Antibodies to St. Louis virus were detected in the sera of fowls and some domestic animals.

PRESENT KNOWLEDGE OF THE EPIDEMIOLOGY

The Rôle of Mosquitoes and Other Arthropods

Mosquitoes.

In the earlier outbreaks, evidence was strong that the disease was spread by mosquitoes, but there was no definite proof Of recent years, however, the work of Hammon and his associates has shown conclusively that mosquitoes, mainly *Culex tarsalis*, are the responsible vectors in Yakima, Washington, and probably elsewhere

Thus, mosquitoes have been found infected in endemic areas, for virus has been recovered from *Culex tarsalis* and *Culex pipiens* obtained in the Yakima Valley, *C tarsalis* is the main vector (Hammon *et al*, 1941 *b*, 1942 *b, c*, 1945, California Mosquito Control Association, 1942, Hammon and Reeves, 1942, 1945, 1947, Reeves and Hammon, 1942). Virus has also been recovered, in California, from *Aedes dorsalis* (Hammon and Reeves, 1945, 1947). The necessary technique has been described by Hammon, Reeves, and Izumi (1942).

The following mosquitoes have been shown capable of transmitting the infection by bite, in laboratory experiments (Hammon and Reeves, 1942, 1943; Hammon, Reeves, and Gray, 1943, Reeves, Hammon, and Izumi, 1942, see also Fulton *et al*, 1940)· *Culex tarsalis, Culex pipiens, Culex coronator, Aedes lateralis, Aedes taeniorhynchus, Aedes vexans, Aedes nigromaculis, Theobaldia incidens, Theobaldia inornata.*

Hammon and Reeves (1945) quote work of Mitamura in which infection was transmitted by *Culex tritaeniorhynchus, Aedes albopictus,* and *Culex pipiens* var *pallens.*

In these experiments, mosquitoes have been infected by a meal of virus-containing material or by biting an infected animal After a few days the infection has been transmitted by bite to chickens, pigeons, doves, and baby mice. Of particular interest is the finding that *Culex tarsalis* can be infected by feeding on chickens and ducks previously inoculated with virus subcutaneously and developing viremia, after a period these mosquitoes transmitted the infection to other chickens, and these developed viremia (Hammon and Reeves, 1943).

C. tarsalis feeds in nature on cows, horses, men, pigs, dogs, chickens, and sheep, and is, therefore, a potent danger as regards the transmission of infection (Bang and Reeves, 1942).

Ticks.

St. Louis virus has been recovered from engorged larval ticks fed on infected Swiss mice, experimentally, infection has been transmitted to young mice by larval ticks (Blattner and Heys, 1941) In later experiments (1943, 1944), it was reported that the female could transmit the infection to her offspring through the egg, and through all stages of metamorphosis to the second generation. It was suggested that

ticks may maintain the infection in lower animals, but that they are not responsible for human infections.

Mites.

St Louis virus has been isolated from chicken mites (*Dermanyssus gallinae*) obtained in the St Louis area, on 7 separate occasions, in nonepidemic periods, mites naturally infected retained virus after 5 months in the laboratory, transfer through the egg to the first stage nymph has been shown (Smith, Blattner, and Heys, 1944, 1945). In later experiments, it was shown that the small amount of virus circulating in the blood of chickens was sufficient to infect fresh mites (1947). Hammon and Reeves (1947) found no evidence that mites were infected in Yakima.

Animal reservoirs.

It has been found that the sera of horses and other domestic animals may contain antibodies to the virus, these antibodies may also be found in the sera of chickens, antibodies have less commonly been found in the sera of wild birds and mammals (Hammon *et al*, 1941 *a*, Hammon, Carle, and Izumi, 1942).

As has been mentioned above, the most important reservoir is probably the chicken, as it develops viremia, and can infect mosquitoes that bite it; other domestic birds may also be responsible.

Conclusions.

Although it is reasonable to postulate the spread of the disease by mosquitoes to fowls, with occasional and accidental involvement of horses and man, the story is far from complete (Hammon and Reeves, 1945) There have been no positive isolations of virus from overwintered mosquitoes, and there is no evidence of transovarial spread It would seem that the demonstration of infection in chicken mites is of considerable importance, although Hammon and Reeves (1945) failed to isolate virus from over 20,000 mites from Yakima in 1944

ANTIGENIC CHARACTERISTICS OF ST. LOUIS VIRUS

The strains isolated in 1933 by numerous workers have been passaged continuously since that date Various strains of virus were isolated from the 1937 outbreak (Greutter *et al*, 1937–8, McCordock *et al*, 1937–8)

Strains isolated in St Louis in 1933 and 1937, Kansas City, Paris, and New York were shown to be immunologically identical (Webster and Fite, 1933, 1933–4, 1935, Greutter *et al*, 1937–8, McCordock *et al*, 1937–8). However, Webster (1940) referred to slight differences between 2 strains

ANIMAL EXPERIMENTS

Mice.

Laboratory mice are highly susceptible to infection, field mice can also be infected (Greutter *et al*, 1940) Young mice are more susceptible to peritoneal inoculation than are older animals, but when virus is inoculated cerebrally or nasally there is no difference in susceptibility depending on age (O'Leary, Smith, and Reames, 1942)

Intracranial injection is the simplest method of transmitting the infection As first shown by Webster and Fite (1933), white-face, Swiss, and other mice are susceptible The virus multiplies rapidly in the brain and reaches a titer of 10^9 intracerebral lethal doses After an incubation period of 3 to 4 days, the fur becomes ruffled and the skin hyperesthetic. Tremors, convulsions, ataxia, paralysis, and prostration follow, and the animal dies within 5 to 9 days after injection (Webster and Fite, 1933, Muckenfuss, Armstrong, and McCordock, 1933, Brodie, 1933–4 *b*)

The pathological features are similar whether the encephalitis follows intracerebral, intranasal, or other route of injection (Webster and Fite, 1933; Smadel and Moore, 1934). Naked-eye, the brain is pink. Microscopically the following changes are found, (*a*) perivascular cuffing with mononuclears, (*b*) focal collections of microglia related to vessels unaffected by cuffing, (*c*) a combination of (*a*) and (*b*), (*d*) degenerative changes in the ganglion cells, chromatolysis, pyknosis, loss of Nissl granules, or neuronophagia, (*e*) infiltration of the meninges and choroid plexuses with mononuclears, (*f*) occasional perivascular hemorrhages; (*g*) perivasc [illegible]
cor[illegible]
are [illegible]
the summer (Lillie *et al.*, 1937).

Intranasal inoculation. Mice can be infected readily by intranasal instillation of virus (Webster and Fite, 1933; Brodie, 1934–5, and many others), and the presence of the virus can be demonstrated in the olfactory bulbs in 24 hours, the pyriform lobes in 24 to 48 hours, the remainder of the brain in 3 days, and the cord in 4 days (Webster and Fite, 1934 *a, b*, Brodie, 1934–5, Webster and Clow, 1936)

Microscopic lesions in the brain follow the arrival of the virus Thus not until the 3rd day do lesions appear in the olfactory bulbs, the 4th day in the pyriform lobes, and the 5th day in Ammon's horn. These lesions take the form of perivascular exudation of mononuclears in the pia, hyperplasia of the pial endothelium, and necrosis of the nerve cells of the olfactory tract (Webster and Clow, 1936) Rake (1937) confirmed the passage of virus to the forebrain after intranasal instillation, this did not occur before 24 hours. This time was much more than that obtained with equine encephalomyelitis virus. Cook (1938 *a*) reported that neither various bacteria nor the viruses of human and swine influenza altered the pathogenicity of St. Louis virus for mice, when sprayed together in the form of a mixture intranasally Occasionally, subclinical infection may develop after nasal inoculation (Slavin, 1943).

Other methods of injection Encephalitis may ensue, especially in young mice, after intraperitoneal or subcutaneous injection, in older animals large doses may infect (Webster and Clow, 1936, Lennette and Koprowski, 1944).

Other routes that have been used include vaginal application (Haber, 1939 *b*), ingestion (Harford and Bronfenbrenner, 1942), or intestinal inoculation (Mezera *et al*, 1941), intratesticular (Lennette and Smith, 1939 *a*, 1940), intramuscular, when glycerol is given peritoneally (King, 1940), intravenous (Peck and Sabin, 1947)

Effects of breeding Webster (1937) selected from a hybrid stock (in which 40 to 50 per cent died after injection of virus) lines in which as high as 95 per cent or as low as 15 per cent died after injection of the virus He suggested that the resistance to St Louis virus is inherited on a single factor basis with resistance dominant over susceptibility (see also Wright, 1940).

Pathogenesis and distribution of virus

When virus is inoculated by peripheral routes, it seems certain that it invades by nerve paths to reach the brain and cord, and cause encephalitis and myelitis, the virus may ascend directly or perhaps by initial blood invasion and excretion into the nasal mucosa (Holden, 1940, O'Leary, Smith, and Reames, 1942)

Virus may be found in the blood shortly after injection, and just before death, in the spleen, and less commonly in other organs (Webster and Fite, 1934 *b*, Webster and Clow, 1936, Kudo *et al*, 1937, Haber, 1938, 1939 *a*) A special study of the dissemination of virus in the body has been made by Peck and Sabin (1947)

1 After intravenous inoculation of large doses, they could only recover at the most about 1/1,000 of the inoculum 4 hours later, and this from the blood, spleen, liver, lungs, and heart. At 24 hours, traces were found in the brain, intestinal tract, tongue, nasal mucosa, hamstring muscles, and inguinal lymph nodes At 48 hours,

72 hours
ct It ap-
eripheral
nerves, as it was found in sciatic nerves, and hamstring muscles. At 96 hours, when the animal was prostrate and the virus concentration in the brain very large, virus was disseminated throughout the body, but the blood and nasal mucosa had only traces. It appeared that virus multiplied primarily only in the CNS, and to a lesser extent in the intestinal tract.

us injection of large
in the CNS Occa-
was primary local-
e posterior extremi-
cur in the lumbar
region, as seen after injection in the muscles of the posterior extremities

2. After intracerebral injection of at least 100 cerebral LD50, no virus could be detected locally after 4 hours. At 24 hours there was evidence of early multiplication in the brain, and a trace of virus was found in the spleen At 48 hours, 4 million LD50 were found in the brain, and centrifugal spread along peripheral nerves was beginning. At 96 hours, the virus concentration in the brain was 3.2 billion LD50, and virus was found in all organs except inguinal nodes and intestinal contents. Virus had evidently "spilled over" into the blood

3 After nasal inoculation, virus quickly reached the lungs, but did not undergo continued multiplication there, at 48 hours there was evidence of commencing multiplication in the brain At 96 hours, the distribution of virus resembled that found in the cerebral group There was no evidence of multiplication in the nasal mucosa.

4 Tests indicated that virus could be present in high concentration in the walls of the intestinal tract, without being liberated in the stools

5 In the terminal stages of the infection, leg muscles, heart, lungs, spleen, tongue, and urinary bladder contained as much virus as, or more than, the sciatic nerves, per unit of weight. As the amount of virus in the blood was negligible, it seems that virus either accumulated in these tissues by diffusion along nerve fibers, or multiplied in some other constituent than nerve fibers.

Prevention or modification of experimental infection of mice.

(*a*) *By inoculation of chemicals* Intranasal inoculations of picric acid, with or without alum, were found to be the most effective means of preventing infection by the same route. Picric acid is thought to act locally on the mucosa, on the virus itself, or on both (Armstrong and Harrison, 1936 *a*) It was found that picric acid solutions have no protective effect unless the pH is such that coagulation of proteins occurs (Armstrong and Harrison, 1936 *b*) Saline (4 per cent) and hypertonic glucose have a similar though less pronounced effect (Armstrong, 1935). Injections of prontosil and related drugs were ineffective (McKinley, Meck and Acree, 1939). Mice showing signs of infection are more susceptible than normal animals to the lethal effects of intraperitoneally injected glucose, due to a dehydrating effect (Hoyt, Holden, and Rawson, 1939).

(*b*) *By x-rays* Mice treated with soft x-rays after intranasal instillation of virus either fail to succumb, or else the incubation and duration periods of the disease are prolonged (Goldberg, Brodie, and Stanley, 1934–5)

(*c*) *Cultures of nonpathogenic bacteria* were found to render mice resistant to intracranial inoculation, the cultures were obtained from the nostrils of mice and were injected intranasally in the test animals (Armstrong, 1938)

(*d*) *An interference phenomenon* has been demonstrated, for a cerebral inoculation of influenza virus interferes with the proliferation of St. Louis virus in the brain (Vilches and Hirst, 1947)

Monkeys.

Tremors, hyperirritability, raised temperature, pareses, apathy, and drowsiness follow the intracranial injection (repeated if necessary) of rhesus monkeys in 8 to 14 days Pathologically the changes are perivascular cuffing, nerve cell degeneration, and focal cellular infiltrations The virus is not readily established in monkeys and dies out with passage, cebus monkeys are insusceptible altogether (Mucken- [illegible] 1933; Webster and Fite, 1933, [illegible] Webster, 1934). Viremia may [illegible]

During the course of passage through monkeys, Armstrong and Lillie (1934) encountered a virus which they named the virus of experimental lymphocytic choriomeningitis (see Ch LXXXIX).

Other animals.

Rabbits are insusceptible to intracranial, corneal, intradermal, and intraperitoneal injections (Brodie, 1933–4 *b*, Webster and Fite, 1935).

Guinea-pigs were said to be insusceptible to intracranial and pad injections (Webster and Fite, 1935; Brodie, 1933–4 *b*), although Sulkin *et al* (1939 *b*) reported some positive results on intracerebral injection

Rats are insuspectible to intracranial, nasal, and intraperitoneal injections (Brodie, 1933–4 *b*, Webster and Fite, 1935). Smith (1939 *b*) reported that virus persisted in the brains of rats and guinea-pigs for 8 to 9 days after injection of virus.

Syrian hamsters can be infected (Lennette, 1941; Broun *et al*, 1941 *a*)

Sheep are insusceptible to intracranial injection (Webster and Fite, 1935).

Kittens and ferrets are insusceptible to injection (Brodie, 1933–4 *b*).

Chickens, ducks, and *doves* develop viremia after subcutaneous injection (Hammon, Reeves, and Izumi, 1946).

Horses can be infected by the cerebral route (Cox, Philip, and Kilpatrick, 1941).

Chicks (newly hatched) develop no definite signs, but virus may be passed in series for a time using brain tissue (Pearson, 1940, Sulkin, Harford, and Bronfenbrenner, 1940).

Morphology and Filtrability

The size has been estimated at from 0 22 μ to 0 33 μ by Elford's filtration method (Bauer, Fite, and Webster, 1933–4), and by Elford and Perdrau (1935) at from 0 20 μ to 0 30 μ (see also Yaoi *et al*, 1939).

As yet no inclusion bodies have been described.

The virus filters through Berkefeld V and N, and Seitz filters (Webster and Fite, 1933, 1935)

Tissue Cultivation

The virus has been grown in various types of tissue culture (Syverton and Berry, 1935, Harrison and Moore, 1936–37, 1937, Schultz *et al*, 1938, Molloy, 1940, Pang, 1940, Pang and Zia, 1940, Webster and Johnson, 1941, Huang, 1943 *a*, *b*)

The Egg

The virus proliferates in the egg after inoculation by the usual routes, the chorio-allantoic membrane being chiefly used (Harrison and Moore, 1936–7, 1937, Schultz *et al*, 1938, Smith, 1939 *a*, 1943 *b*, Smith and Lennette, 1939, Blattner and Heys, 1946, Smith, Blattner, and Heys, 1947)

The chorio-allantoic *route can be used for the titration* of viruses, and neutralizing antibodies (Blattner and Cooke, 1942).

It has been reported that western equine encephalitis virus grows only to a

limited extent when inoculated in eggs supporting the growth of St Louis virus (Duffy, 1944).

Reaction to Physical and Chemical Agents

Virus in the form of brain suspension rapidly loses infectivity in the ordinary ice chest. Infectivity is well maintained in vials in the dry ice chest. Glycerol is said to preserve infectivity for some months. Infectivity may be preserved for prolonged periods in frozen dried brain tissue (Lennette and Smith, 1939 *b*, Wooley, 1939)

Infectivity is not well preserved in saline, and serum or skimmed milk should be used (see, e g., Cook and Hudson, 1937). The optimum pH for stability (in glycine phosphate buffer) is 8 4–8 8 (Duffy, 1946).

As regards heat, infectivity is lost in half an hour at 56° C. (Kudo *et al.*, 1937).

Virus can be inactivated by exposure for a brief period to a suitable source of ultraviolet light, such preparations are antigenic (Levinson *et al*, 1944, 1945).

Soft x-rays also inactivate virus (Moore and Kersten, 1937).

Virus is inactivated by 0 1 per cent. formalin in 10–18 hours at room temperature, but resists 1 per cent phenol for 25 days, and ½ per cent for 50 days (Brodie, 1933–4 *b*)

The virus is sensitive to ether *in vitro*; ether anesthesia alters the course of infection with the virus, but this is unlikely to be due to a direct virucidal effect (Sulkin, Zarafonetis, and Goth, 1946, Sulkin and Zarafonetis, 1947)

Penicillin has not been shown to exert any virucidal effect in eggs or tissue cultures (Parker and Diefendorf, 1944). Numerous chemotherapeutic agents were tested by Kramer, Geer, and Szobel (1944), but none was shown to have any action

IMMUNITY

Active Immunity

It has been shown that mice can be actively immunized by intranasal inoculation (Armstrong, 1934, 1935) and subcutaneous and intraperitoneal injections (Webster and Fite, 1934 *a*, *b*; Webster, 1938, Hodes, 1939).

The immune state develops in 7 days or so, and is manifested by resistance to further injections of virus The immunity lasts for 4 to 6 weeks, and has disappeared [illegible] ially immune [illegible] (Armstrong, [illegible] reinoculated intracerebrally or nasally with virus 7 to 21 days after one or two previous injections [illegible] laccid [illegible] velop [illegible] days when the reinoculation was intracerebral, and after 11 to 14 days when intranasal Histologically the cords of paralyzed mice showed vascular congestion, perivascular and more diffuse round cell infiltration, with microgliosis and degeneration of nerve cells

Hodes (1939) reported that it was much easier actively to immunize virgin than pregnant mice Sulkin *et al* (1939 *a*) immunized mice with intranasal inoculation of nasopharyngeal [illegible]

The local use o [illegible] eveloping after nasal instillation of [illegible]

Virus propagate [illegible] properties for mice (Smith, 1943 *b*)

Sabin (1943) has shown that immunity to peripheral challenge can be produced in mice by the inoculation of formolized lyophilized brain suspension Virus in-

activated by ultraviolet light also induces a high degree of resistance (Levinson *et al.*, 1944, 1945).

Virus Neutralizing Antibodies

Antibodies that neutralize the infectivity of St. Louis virus develop in the sera of animals on recovery from infection, or after vaccination with live or inactivated virus.

Virus neutralizing antibodies are usually titrated by inoculation of virus-serum mixtures intracerebrally in mice, and standard procedures have been described by Hammon and Izumi (1942), and Olitsky and Casals (1947, see also Ch. XI). Antibodies can also be titrated in susceptible young mice, injections being subcutaneous in 3-day animals, and peritoneal in animals of 8–28 days, the younger the animal, the greater the amount of neutralization demonstrated (Lennette and Koprowski, 1944).

It has been found that the lipoid fraction of certain normal animal sera rapidly reduces the infectivity of St Louis virus (Casals and Olitsky, 1947)

The sera of certain Brazilian marsupials and rodents neutralizing yellow fever virus also inactivated one or more of the following, Japanese, St Louis, and West Nile viruses, not known to occur in S. America; the inactivating substance resisted 56° C. (Koprowski, 1946).

If pregnant mice are immunized, transmission of antibodies occurs, and this may give rise to a degree of resistance in the sucklings (Smith, 1943 *a*, Slavin, Hale, and Berry, 1946).

Antibodies develop in convalescence from the human disease, and are usually found after about 10–14 days, the antibody titer remains high for some years, antibody also develops on recovery from a subclinical attack (Barr, 1934, Wooley and Armstrong, 1934, Webster, Fite, and Clow, 1935, Muckenfuss, Smadel, and Moore, 1938, Smith and Moore, 1938, Howitt, 1943)

Maternal transmission of antibodies may occur in young children (Hammon *et al*, 1945).

Convalescent serum has been used in prophylaxis and treatment (Slesinger, 1936)

Complement Fixation

Complement fixation can be demonstrated between antisera and various types of [illegible] exposing to ultraviolet light, [illegible] Palacios, 1941, Casals, 1942, [illegible] *was imparted to* mouse brain or chick embryo antigens by extraction in the lyophilized state with benzene, toluene, or dichlorethylene (DeBoer and Cox, 1947; Espana and Hammon, 1947, Hammon and Espana, 1947)

Complement fixation can be used in the diagnosis of the disease in man (Howitt, 1943, Casals, 1945)

Miscellaneous Reactions

It has been reported that virus-coated bacteria are clumped by antisera (Roberts and Jones, 1941, 1942, Roberts, 1945)

Mechanism of Resistance

Various observations suggest that there is little correlation between the presence of serum antibodies and resistance to challenge Thus Webster (1938) found that at the time of maximum resistance to reinoculation, no antibodies could be demonstrated Hodes and Webster (1938) found that after vaccination, mice were resistant to cerebral challenge within one week, and that this resistance was at a high level for 6 weeks, then waning to disappear between the 12th and 20th weeks

They could not demonstrate virus neutralizing antibody until 8 weeks after vaccination. The antibodies were at their highest after 23 weeks, when the degree of resistance was low Observations of similar significance were made by Casals (1943) in mice, complement fixing antibodies developed equally well in those showing or not showing resistance.

Working with hamsters, Broun *et al* (1941 *b*) concluded that the presence of humoral antibodies did not insure resistance.

RELATIONSHIP TO OTHER VIRUS INFECTIONS

Japanese Encephalitis and West Nile Viruses

The virus of St. Louis is closely related to these 2 viruses, which form a subgroup in the group of neurotropic viruses

Certain differences can be detected between the behavior of St Louis and Japanese viruses Thus Kudo *et al.* (1937) concluded that. in mice injected cerebrally, paresis is commoner with the Japanese virus; after intraperitoneal or subcutaneous injection, St Louis virus rarely produces encephalitis, but this is more common with Japanese virus, monkeys are more susceptible to the Japanese than the St. Louis virus

Antigenically Japanese and St Louis viruses are closely related The Japanese [illegible] protective power [illegible] the Japanese virus [illegible]). [illegible] West Nile virus, [illegible] here that in active [illegible] between the three agents (Smithburn, 1942, Casals, 1944). In neutralization tests, definite cross reactions occur, both St. Louis and Japanese sera neutralizing the West Nile virus (Smithburn and Jacobs, 1942, Casals, 1944) West Nile sera only neutralize the other two viruses if of high titer (Casals, 1944).

There seems little doubt that the two agents share common antigens, and that Japanese virus is the most, and West Nile the least, complete of the three, St Louis virus occupying an intermediate position (see also Lennette and Koprowski, 1946)

Encephalitis Lethargica

The isolation of the characteristic virus from cases of St Louis encephalitis renders any relationship with encephalitis lethargica unlikely In confirmation of this, the sera of a number of acute encephalitic and of parkinsonian cases showed no virus neutralizing powers for St Louis virus (Brodie, 1933–4 *a*, Webster, Fite, and Clow, 1935).

Other Viruses

No relationship has been disclosed by neutralization or complement fixation tests with herpes, poliomyelitis, lymphocytic choriomeningitis, rabies, equine encephalomyelitis, vesicular stomatitis, louping ill, blue tongue, and fox encephalitis (Cox and Fite, 1933–4, Webster and Fite, 1933, 1933–4, Webster, Fite, and Clow, 1935, Howitt, 1937)

According to Casals (1944) the West Nile, Japanese, and St Louis viruses are unrelated to the viruses of spring-summer encephalitis, louping ill, or western equine encephalomyelitis Russian observers, however, claim that Russian and louping ill viruses are related antigenically to Japanese and St. Louis viruses (see Ch. XCVIII) The group is not related antigenically to Bunyamwera virus (Smithburn, Haddow, and Mahaffy, 1946), Anopheles A virus (Roca-García, 1944), or Colorado tick fever virus (Koprowski and Cox, 1947).

CHAPTER XCIV

JAPANESE TYPE B ENCEPHALITIS

Two types of epidemic encephalitis occur in Japan, the ordinary or von Economo's encephalitis lethargica (type A), and "summer" or type B encephalitis (Kaneko and Aoki, 1928).

Type A differs in no important essential from the description of encephalitis lethargica given above (Ch. XCII). Although cases of Type B or summer encephalitis have probably been recognized in Japan since the middle of last century, it is only comparatively recently that any serious bacteriological investigations have been made. Numerous workers have isolated strains of virus from the various outbreaks The disease bears considerable resemblance clinically and epidemiologically to St. Louis encephalitis (Ch. XCIII) and the viruses have similar characteristics, although differing antigenically.

The best known outbreak of summer encephalitis occurred between July and September 1924 when some 7,000 persons, mainly in the Kagawa district, were affected (see Takaki, 1925, 1926 *a*, Kaneko, 1925). Since that date outbreaks of varying severity have occurred, but the incidence is variable and in some years only a few cases are reported. A useful general review of the disease is that of Warren (1946).

CLINICAL FEATURES

The characteristic clinical features have been recorded by a number of authors (e.g, Takaki, 1925, 1926 *a*, Kaneko, 1925; Kaneko and Aoki, 1928, who give an extensive Japanese bibliography, Naka, Kingo, and Kuroiwa, 1934, Hashimoto *et al*, 1936).

Onset. For a few days there may be prodromal symptoms of loss of appetite, drowsiness, and nausea, then comes the onset of the disease proper. The temperature rapidly rises and the patient becomes acutely ill Pains may be present in the head, chest, hips, or joints

The course is manifested by both encephalitic and meningitic symptoms

The encephalitic symptoms consist mainly of impairment of the mental faculties, at first there is restlessness, and even delirium, but after a few days apathy sets in. The patient's face is impassive and expressionless. In severe cases this apathy deepens into coma Various muscular movements such as athetosis, myoclonus, and twitchings of the face, hands, and tongue may occur On the other hand, aphasia, motor pareses of the extremities and tongue, and decreased response to painful stimuli may be found. The eye muscles are only rarely affected, apart from some slight contraction of the pupils

The meningitic reaction is evidenced by the presence of Kernig's sign, trismus, rigidity of the neck and limbs, and headache The abdominal reflexes are usually absent and the ankle and knee jerks exaggerated Incontinence or retention of urine may occur.

The fever usually lasts for 5 days or so to fall by lysis The course of the disease is seldom prolonged over 2 weeks If death occurs it is usually before the end of the second week

As regards residua, parkinsonism may occasionally be found, and there may be some persistence of headache, sleeplessness, irritability, neuralgia, neurasthenia, athetosis, pareses, and mental imbalance (see Sakurai and Ito, 1937)

Zimmerman (1946) reported the following features in a carefully studied outbreak on Okinawa: sudden onset with fever and headache, neck rigidity, Kernig's

sign, stupor, loss of speech, general convulsions, flaccid paralysis, Babinski's sign, and absent abdominal reflexes. In 4 proved cases on Korea, Sabin *et al.* (1947 *b*) referred to mental confusion, purposeless movements, convulsions, speech defects, deep stupor, or coma.

CLINICAL PATHOLOGY

Cerebrospinal fluid The cerebrospinal fluid is usually clear, the pressure moderately raised, and there is a pleocytosis up to 1500 cells per c.mm These cells are mainly lymphocytes, although in the early stage polymorphs may be found (Kaneko, 1925; Kaneko and Aoki, 1928, Hashimoto *et al*, 1936).

Blood The blood may show a polynucleosis up to 18,000 per c mm., although 11,000 is an average figure, the Schilling count shows a shift to the left (Matsumura *et al*, 1934, Hashimoto *et al.*, 1936). The red cells and hemoglobin may be slightly but correspondingly reduced, thus maintaining a color index of unity. In severe cases there is a moderate or pronounced acidosis with some hyperglycemia (Naka *et al*, 1934).

MORTALITY

The mortality has always been high, but to a certain extent varies from year to year Thus in 1873 the rate was 80 to 90 per cent., from 1901 to 1927, 55 to 60 per cent (Kaneko and Aoki, 1928), and in 1935 less than 30 per cent (Hashimoto *et al.*, 1936) These and many other authors have commented on the striking increase of severity with advancing age Thus, while under 11 the mortality rate was 47 per cent., from 11 to 20 years it was 40 per cent., and over 80 years it rose to 92 per cent.

PATHOLOGY

The pathological features have been recorded by a number of workers (e.g., Flexner, 1928, Kaneko and Aoki, 1928, Kingo, 1935 *a*, *b*, Hashimoto *et al*, 1936, Pette, 1938).

Naked-eye, the meninges are somewhat edematous, there is a moderate increase in the amount of cerebrospinal fluid, and congestion gives the gray matter of the cortex, basal nuclei, and pons a pinkish appearance. Histologically, perivascular cuffing with lymphocytes is found. There are also some focal infiltrations of mononuclears in the meninges, cortex, and brain stem. Degenerative changes are to be found in the nerve cells of the basal nuclei, pons, and medulla (particularly marked in the substantia nigra). Small foci of necrosis may be found. Bertrand and Miyashita (1936) have described cases in which definite plaques of demyelination were found.

Kingo, in particular, has described a diffuse polynuclear infiltration in the cerebrum, basal nuclei, and less commonly in the cord. He has also noted the occurrence of the iron reaction in the capillary endothelium and neighboring oligodendroglia

Zimmerman (1946) made a detailed study of some cases occurring on Okinawa Naked-eye, little was to be seen in acute cases, but in 3 persons living for more than a month, he found pale or "gritty" patches in the cortical and central gray matter, especially in the pallidal and red nuclei, thalami, and substantia nigra. Cystic changes were seen in the pallidal nuclei and substantia nigra. He described microscopic inflammatory and degenerative changes as recorded by the Japanese, and drew attention to neuronophagia of the anterior horn cells There was a widespread distribution of foci resembling those of disseminated sclerosis, limited to collections of ganglionic cells, in these areas there was an absence of myelin fibers In the cerebellum, there was injury to the Purkinje cells. The "gritty" foci were seen to be due to deposition of calcium, which led to a foreign body giant cell response

The features of a proved case in Korea were described by Sabin *et al* (1947 *b*).

Changes were limited to the gray matter and consisted of neuronal necrosis and neuronophagia. The lesions were present throughout the cerebral cortex, and in the Purkinje and molecular cell layers of the cerebellum.

As regards the relationship, on pathological grounds, between Japanese and von Economo's encephalitis, Kaneko and Aoki draw attention to the following comparatively unimportant points of difference: in Japanese encephalitis there is a greater tendency to formation of abscesses, a more widespread cellular infiltration, a more pronounced meningeal reaction, and more destruction of ganglion cells. If the reports of the occurrence of demyelination are confirmed then it would appear that there is a definite difference between the two histological pictures.

LABORATORY DIAGNOSIS

After death, the virus may be isolated from suspensions of brain and cord by inoculation in mice cerebrally, and in young mice peritoneally. Some mice will die after a few days. Brain suspension should be passed in series, and a portion used for neutralization and fixation tests with known sera (Sabin *et al.*, 1947 *b*).

In nonfatal cases, it may be worth while inoculating cerebrospinal fluid in a number of mice cerebrally and in young mice peritoneally.

The brain of fatal cases may perhaps contain complement fixing antigen, and it has been suggested that a direct fixation test be tried between this material and known serum (Sabin *et al.*, 1947 *b*).

As regards serological tests in nonfatal cases, the neutralizing antibody develops quickly and a very high neutralization index should be obtained after a comparatively short time. The complement fixation test is also of value.

EPIDEMIOLOGY

General Features

The disease has characteristically occurred in Japan in large epidemics. Practically every outbreak has taken place in the months of August and September, in the dry, hot weather. The most serious outbreaks occurred in 1924, 1927, 1929, and 1935 (see Iimura, 1936, Inada, 1938). Outbreaks have been rare of recent years. Thus, Sabin, Ginder, and Matumoto (1947) give these figures: 1939, 2,720, 1940, *529, 1941, 248, 1942, 407, 1943, nil, 1944, 12, 1945, 12.*

The highest incidence of cases is among peasants, but nonJapanese may be attacked.

As regards sex, there is a slightly increased liability to infection in men as *against women (1.26: 1, Kaneko and Aoki, 1928). Approximately 75 per cent* of cases have been reported as occurring in persons over the age of 40 (Naka, Kingo, and Kurowa, 1934), although there have been suggestions as to a recent alteration to involve children more frequently.

Geographical Incidence

Japan. The disease has been reported in many parts of Japan, especially around the Inland Sea, it occurs from Hokkaido in the North to the Ryukyu Islands in the South. Virus has also been isolated in Formosa (Kobayasi, 1940).

Korea. Hitherto this island has been thought to be free of the infection, but Sabin *et al.* (1947 *b*) described 4 cases in U.S. soldiers in 1946. Although native Koreans did not appear to suffer from encephalitis, a high percentage of adult sera neutralized the virus, suggesting a widespread dissemination of virus in the absence of epidemics—a position analogous to that present in China (see below).

Okinawa. Summer encephalitis is probably endemic in natives, and attacks the younger age groups, during World War II there were some military cases in U.S. forces, the evidence pointed to mosquito spread from horses or goats, some of

whose sera contained antibody (Hodes, Thomas, and Peck, 1945, 1946, Thomas and Peck, 1946, Zimmerman, 1946, Sabin, 1947 *b*).

China. Various reports confirm the presence of the infection in China, and the virus has been isolated and significant rises in serum antibody detected Thus encephalitis due to the Japanese virus has been identified as occurring in Peiping (Chu, Wu, and Teng, 1940, Huang and Liu, 1940, Huang, 1941, Yen, 1941), and Shanghai (Sabin, Schlesinger, and Ginder, 1947) It is probable that the virus is widely distributed in China, but that inapparent infections are more common than encephalitis Thus, Sabin, Schlesinger, and Ginder (1947) found virus neutralizing antibodies in the sera of 17/19 Chinese in Tientsin, and 11/13 in Shanghai. They quote Mitamura as having found that the sera of 83 per cent. of 104 normal persons in Nanking and Shanghai neutralized the virus

Russia autumn encephalitis A form of encephalitis occurring in the autumn in the Far East of Russia, and quite distinct from spring-summer encephalitis, is due to the virus of Japanese encephalitis The infection is spread by *Culex pipiens* and *C tritaeniorhynchus* (Smorodintsev, Shubladze, and Neustroev, 1940), other mosquitoes incriminated are *C. bitaeniorhynchus*, *Aedes japonicus*, and *Aedes esoensis* (Chagin and Kondratiev, 1943, Chagin, 1946).

Arthropod Transmission

[illegible] ed that the disease is *mosquito-* [illegible] (1937, 1938, 1939) has confirmed [illegible] (*Culex pipiens* var. *pallens*, and [illegible] outbreak transmitted the infection to mice by bite. (2) *Culex pipiens* var *pallens* mosquitoes were shown to become infected by feeding on virus suspension or by biting an infected mouse, they could then transfer the infection to fresh mice by biting (3) With *Culex pipiens* var *pallens*, they were able to demonstrate transovarial infection Russian observers have also incriminated mosquitoes in autumn encephalitis (see above)

In the United States, Reeves and Hammon (1946) undertook studies on mosquito transmission, with the possibility in mind that Japanese encephalitis might become established in North America They found that the following mosquitoes could be infected by feeding on virus suspension, and after a period of 6–25 days were infective for mice by biting *Culex pipiens var molestus, Culex pipiens* var. *pipiens, Culex quinquefasciatus, Culex tarsalis, Aedes nigromaculis, Aedes dorsalis, Culiseta incidens, and Culiseta inornata*

Bearing in mind the state of affairs in St Louis and equine encephalitis, it seems likely that there is some reservoir of infection in animals. The position is obscure, but antibodies have been detected in dogs (Mitamura *et al*, 1939), and in horses, goats, cattle, and rabbits (see above—Okinawa, also Sabin, Ginder, and Matumoto, 1947). Viremia occurs in experimentally infected horses (Thomas and Peck, 1946), chickens (Hammon, Reeves, and Burroughs, 1946), and virus persists in the blood of pigs and ducks for 24 hours after intravenous injection (Meiklejohn, Simpson, and Stacy, 1947)

It is obvious that much further work is required in Japan, analogous to that carried out by Hammon and his associates in America

It must not be overlooked that *ticks* may play some part Russian observers have found that virus may persist for several months in *H turkmeniense*, and transovarial infections may occur in this and other species (Chumakov, Petrova, and Sondak, 1945)

On the strength of finding antibodies in the sera of Japanese horses, goats, cattle, and rabbits, but not chickens or children, it has been suggested that in nonepidemic periods other arthropod vectors than mosquitoes may be involved, the possible rôle of helminths should not be overlooked in the transmission of infection between animals (Sabin, Ginder, and Matumoto, 1947).

PROPERTIES OF THE VIRUS

One of the earliest reports of the isolation of a virus from the 1924 cases was that of Kobayashi (1925). This virus aroused some interest at the time until Cowdry's (1927) discovery that it was a strain of rabies.

A large number of Japanese workers has isolated strains of virus from the brain or cerebrospinal fluid of cases since 1925, and the following is a list of many of these names· Takaki (1925, 1926 *a*, *b*); Ito *et al.* (1925 *a*, *b*), Nishibe (1925 *a*, *b*, 1926), Kojima and Ono (1925); Komatsu and Yamasaki (1925); Kaneko and Aoki (1928), Hayashi (1934), T...
Hashimoto *et al.* (1936); K...
hensive general review is gi...
of the strains isolated by th...
acteristics. These will now...

Animal Experiments

Rabbits Rabbits have been infected by a number of routes. e g, cerebral, corneal, intra-ocular, nasal, and testicular (Takaki, 1925, 1926 *a*, Nishibe, 1925 *a*, *b*, 1926, Taniguchi *et al*, 1935, Hashimoto *et al*, 1936, Kasahara *et al*, 1936 *b*, Kudo *et al.*, 1937) After peripheral injection, the virus can be found in the blood within 24 hours and remains there up to 4 days After intracerebral injection, the characteristic symptoms develop in a few days, namely, sleepiness, dyspnea, pupillary constriction, fever, and paresis of all limbs.

After intra-ocular injection, iridocyclitis occurs with glaucoma and atrophy. After corneal injection, keratoconjunctivitis develops. After testicular injection, orchitis develops in 3 to 5 days, but after repeated passage it occurs in 24 hours

Rabbits most frequently die in the 2nd week of the infection Histologically, after intracerebral injection, there is definite degeneration to be found in the cells of the midbrain and thalamus, there are also other characteristic encephalitic lesions The virus is found widely distributed in brain, cord, blood (both whole and plasma), and internal organs.

Guinea-pigs The virus can be passaged by intratesticular injection (Kasahara *et al*, 1936 *a*, *b*). Testicular virus can be transmitted to guinea-pigs by a number of other routes (Kasahara *et al*, 1936 *b*). Hammon and Espana (1947) report that only fever follows cerebral inoculation

Mice Encephalitis develops after intracerebral, nasal, intraperitoneal, testicular and subcutaneous injections (Kawamura *et al*, 1936 *a*, *b*, Kasahara *et al*, 1936 *a*, *b*, Taniguchi *et al*, 1936, Hashimoto *et al*, 1936, Kudo *et al*, 1937, Webster, 1938, Kobayashi, 1940, Lennette and Smith, 1940). After 3 to 4 days the fur becomes ruffled, the skin hyperesthetic, and tremors, convulsions, and pareses appear The animals frequently die, and microscopically the brain shows widespread perivascular ... tion The meninges
...idely distributed in
... virus passes to the
... eneralized infection
of the central nervous system follows

As regards extraneural injection, it is chiefly young mice that are susceptible, resistance developing after about 2 weeks (Lennette and Koprowski, 1944)
... iturally infected with the virus
(K... on various experiments using
mic...

Monkeys Monkeys can be infected by ocular and intracranial injection and by nasal instillation, young macaques being the most susceptible (Kaneko and Aoki,

1928, Hayashi, 1934, Taniguchi *et al*, 1935, 1936, Kawamura *et al.*, 1936 *a*, *b*; Webster, 1938, Kobayashi, 1940).

After corneal inoculation, Taniguchi *et al* discovered Guarneri-like bodies in the epithelium Up to 72 hours these bodies were intracellular, but thereafter they escaped and split up into elementary bodies of 0 25 μ diameter.

After intracranial injection, an incubation period of some 4 to 7 days elapses before symptoms appear, namely, neck rigidity, convulsions, and somnolence. Nystagmus, unequal pupils, ptosis, and salivation may be found Histologically, the pia is congested and infiltrated with lymphocytes Perivascular infiltration, nerve cell degeneration, neuronophagia and glial proliferation are widespread, but are most marked in the basal ganglia, midbrain, and pons. The virus is to be found in the blood and nasal washings of infected animals

After nasal inoculation the virus produces a local reaction, and then spreads to the brain via the olfactory nerves and bulbs Meningitis is found most marked basally, and infection of the whole brain follows thereafter.

Other animals The Syrian hamster is highly susceptible (Lennette, 1941). Sheep can be infected cerebrally or nasally (Webster, 1938). Chickens develop viremia after subcutaneous injection (Hammon, Reeves, and Burroughs, 1946). Transient viremia occurs in horses, pigs, and ducks after intravenous injection (see above). White rats can be infected by intratesticular injection (Kasahara *et al*, 1936 *b*)

Insusceptible animals The following usually prove refractory to injection of the virus dogs, cats, goats (Kawamura *et al*, 1936 *a*, *b*).

Morphology

Elementary bodies staining by Giemsa, and Guarnieri-like bodies in the epithelium were described in corneal preparations by Taniguchi *et al* (1935), but their significance is doubtful.

The virus passes the following filters Berkefeld N, W, Seitz EK, and Mandler (Takaki, 1926 *a*, Kawamura *et al*, 1936 *a*, *b*, Taniguchi *et al*, 1936, Kasahara *et al*, 1936 *a*, Kudo *et al*, 1937)

Filtration experiments show the size to be 20–30 mμ (Yaoi *et al*, 1939).

Cultivation

The virus has been grown in tissue culture (Haagen and Crodel, 1938, Kawakita, 1939).

Various workers have demonstrated the susceptibility of the fertile egg (Taniguchi *et al.*, 1936, Haagen and Crodel, 1938, Smith and Lennette, 1939) Of more recent years this question has been further explored, mainly with a view to vaccine production, and the following points have been demonstrated (Howitt, 1946, Koprowski and Cox, 1946 *a*, *b*, Morgan, Early, and McClain, 1946, Warren and Hough, 1946) The egg can be infected by all routes, especially by the yolk sac After inoculation, virus proliferates rapidly and reaches highest titer in the embryo Virus suspension can be titered, e g, by yolk sac inoculation Chick embryo tissue has been used in vaccine production (see below).

Reaction to Physical and Chemical Agents

The virus is destroyed at 55° C in ½ to 1 hour At 0° C. it survives for 3 weeks. It preserves its infectivity, especially in glass sealed tubes at −70° C. for a prolonged period, −20° C is not so efficient (Melnick, 1946) In glycerol it conserves its virulence for fully 7 months It is destroyed by bile (Takaki, 1925, 1926 *a*, Kudo *et al*, 1937) Virus loses its infectivity fairly quickly in saline, but proves more stable in 10 per cent serum or skimmed milk; the optimum pH is between 7 5 and 8 5 (Hirano and Koyama, 1939, Duffy and Stanley, 1945).

PROPERTIES OF THE VIRUS

One of the earliest reports of the isolation of a virus from the 1924 cases was that of Kobayashi (1925). This virus aroused some interest at the time until Cowdry's (1927) discovery that it was a strain of rabies.

A large number of Japanese workers has isolated strains of virus from the brain or cerebrospinal fluid of cases since 1925, and the following is a list of many of these names: Takaki (1925, 1926 *a*, *b*), Ito *et al.* (1925 *a*, *b*); Nishibe (1925 *a*, *b*, 1926); Kojima and Ono (1925); Komatsu [illegible] (1928); Hayashi (1934); Taniguchi *et al.* ([illegible] Hashimoto *et al.* (1936); Kasahara *et al* [illegible] hensive general review is given by Inada (1937). It may be said that the great bulk of the strains isolated by these workers resemble each other in their general characteristics These will now be described.

Animal Experiments

Rabbits. Rabbits have been infected by a number of routes: e.g, cerebral, corneal, intra-ocular, nasal, and testicular (Takaki, 1925, 1926 *a*, Nishibe, 1925 *a*, *b*, 1926, Taniguchi *et al.*, 1935; Hashimoto *et al*, 1936, Kasahara *et al.*, 1936 *b*, Kudo *et al.*, 1937). After peripheral injection, the virus can be found in the blood within 24 hours and remains there up to 4 days. After intracerebral injection, the characteristic symptoms develop in a few days, namely, sleepiness, dyspnea, pupillary constriction, fever, and paresis of all limbs

After intra-ocular injection, iridocyclitis occurs with glaucoma and atrophy. After corneal injection, keratoconjunctivitis develops. After testicular injection, orchitis develops in 3 to 5 days, but after repeated passage it occurs in 24 hours.

Rabbits most frequently die in the 2nd week of the infection. Histologically, after intracerebral injection, there is definite degeneration to be found in the cells of the midbrain and thalamus, there are also other characteristic encephalitic lesions The virus is found widely distributed in brain, cord, blood (both whole and plasma), and internal organs.

Guinea-pigs. The virus can be passaged by intratesticular injection (Kasahara *et al*, 1936 *a*, *b*). Testicular virus can be transmitted to guinea-pigs by a number of other routes (Kasahara *et al*, 1936 *b*) Hammon and Espana (1947) report that only fever follows cerebral inoculation.

Mice. Encephalitis develops after intracerebral, nasal, intraperitoneal, testicular and subcutaneous injections (Kawamura *et al*, 1936 *a*, *b*, Kasahara *et al.*, 1936 *a*, *b*, Taniguchi *et al*, 1936, Hashimoto *et al*, 1936, Kudo *et al.*, 1937, Webster, 1938, Kobayashi, 1940, Lennette and Smith, 1940) After 3 to 4 days the fur becomes ruffled, the skin hyperesthetic, and tremors, convulsions, and pareses appear. The animals frequently die, and microscopically the brain shows widespread perivascular lymphocytic cuffing, lymphocytic infiltration, and glial proliferation. The meninges are hyperemic and infiltrated with lymphocytes The agent is widely distributed in the brain, blood, and internal organs After nasal instillation, the virus passes to the base of the brain by the olfactory nerves and bulbs, and a generalized infection of the central nervous system follows.

As regards extraneural injection, it is chiefly young mice that are susceptible, resistance developing after about 2 weeks (Lennette and Koprowski, 1944) [illegible] iturally infected with the virus [illegible] on various experiments using [illegible]

[illegible] l intracranial injection and by nasal instillation, young macaques being the most susceptible (Kaneko and Aoki,

on the 5th day of the disease, indicating that antibody can play little part in protection.

Antibody also develops after subclinical attack (Kudo *et al.*, 1937, Mitamura *et al*, 1939). Recent observations in Japan suggest that antibody is now very rare in children under 10, but is present in many adults (Sabin, Ginder, and Matumoto, 1947)

These antibodies are tested by the cerebral route in adult mice (Olitsky and Casals, 1947, see Ch XI; Sabin, 1947 *b*) or by inoculation subcutaneously in 3-day mice (Lennette and Koprowski, 1946), or peritoneally in somewhat older mice.

Certain observations suggest that normal animal and human serum may contain nonspecific virus neutralizing substances (Kasahara *et al*, 1937 *a*, Sabin, 1943) Koprowski (1946) found that the sera of certain marsupials and rodents captured in Brazil, chiefly *Didelphis marsupialis*, and members of the genus *Oryzomys*, that neutralized the virus of yellow fever, also inactivated one or more of Japanese B, St. Louis, and West Nile viruses, not known to occur in Brazil This nonspecific substance was not destroyed at 56° C A lipoid fraction of normal animal serum rapidly inactivates Japanese virus (Casals and Olitsky, 1947).

It has been shown with rabbit sera that the gamma globulin fraction is protective and not the albumin (Koprowski, Richmond, and Moore, 1947).

Complement fixation occurs between [illegible] itable antigens Thus [illegible] More lately various [illegible] freezing and thaw- [illegible] exposure to UVL (Havens *et al*, 1943), by heating and clarification by centrifugation (Casals, 1945), and by a mixture of the above methods, the resultant antigen being lyophilized for storage (Casals, 1947, see also Ch XI) DeBoer and Cox (1947) claim to have produced a highly specific antigen by extraction in the lyophilized state with benzene, toluene, or dichlorethylene This procedure has been modified by Espana and H[illegible] 47) They prepare high titer [illegible] r develop- ing (Hammon [illegible] in man a few days after [illegible] some weeks (Zimmerman, 1946, [illegible] Simpson, and Stacy, 1947; Sabin, 1947 *b*, Sabin *et al*, 1947 *b*) Sabin points out that the virus neutralizing antibody persists longer than the complement fixing, and that the presence of high titer complement fixing antibodies suggests a recent infection (see also Sabin *et al*, 1947 *b*).

Precipitation has been reported between serum and a filtered boiled brain suspension (Takaki, 1925)

RELATIONSHIP TO ST. LOUIS ENCEPHALITIS AND ENCEPHALITIS LETHARGICA

On clinical and epidemiological grounds, Japanese Type B encephalitis closely resembles St Louis encephalitis Pathologically it presents points of resemblance both to this disease as well as lethargic encephalitis

The Japanese virus resembles very [illegible]

[illegible] does not protect against injec- [illegible] virus, although Japanese antiserum (animal) may show some protective properties against both viruses Of recent years it has been found that the West Nile virus is also related, and it appears reasonable to place the 3 in a subgroup, Japanese virus being the most comprehensive antigenically, West Nile being the least comprehensive, with St Louis occupying an intermediate position (see Ch XLVII for a full discussion).

It may be concluded, therefore, that the two forms of encephalitis, Japanese and

IMMUNITY

Active Immunity

Animals that recover from experimental infection become immune to reinoculation. This result can also be brought about by the administration of a vaccine, or of live virus by a route that does not normally lead to a fatal outcome In man, immunity almost certainly arises in many instances by subclinical infection During World War II, American investigators explored the possibility of producing vaccines on a large scale, for use in Japan and other endemic areas in the Far East. Two vaccines were produced.

Mouse brain vaccine. Experiments of Duffy and Stanley (1945) suggested that it was not possible to secure by the centrifugation of mouse brain a preparation of virus sufficiently concentrated and free from mouse tissue to be used for vaccine production on a large scale. However, Sabin and his associates have introduced a relatively crude form of vaccine that has been used on a fairly large scale by American forces (Sabin, 1943, 1947 *b*). The vaccine consists of 10 per cent mouse brain suspension inactivated with 0 2 per cent. formaldehyde. Injected in mice in 2 doses, the vaccine stimulated resistance to infection by the peritoneal route, and injected in larger doses, immunized against cerebral or nasal challenge.

Two or 3 injections are given in man. There have been no reports of demyelinating reaction (Sabin, 1947 *b*). About 50 per cent. of persons vaccinated develop neutralizing antibodies after the 3rd dose, complement fixing antibodies rarely develop (Ginder *et al.*, 1947, Sabin, 1947 *a*, Sabin and Duffy, 1947). Sabin *et al* [illegible] 's compared to persons [illegible] not the older people, [illegible] who had neutralizing antibody prior to inoculation (presumably due to old infection) but not in old people without such antibody.

Chick embryo vaccine Warren and Hough (1946) worked with homogenized infected embryos, and added formalin to a final concentration of 0 2 per cent., the final concentration of chick tissue being 10–20 per cent The vaccine was shown to be antigenic in mice A similar type of vaccine was used by Koprowski and Cox (1946 *b*) Using the method of assay introduced by Sabin (above), the chick vaccine did not reach the specified requirements However, mice vaccinated with chick vaccine showed a much higher degree of resistance when challenged with live homologous (chick cultivated) virus, and not with mouse brain If mice were vaccinated peritoneally with chick vaccine, and challenged intravenously with chick cultivated virus, the immunogenic powers of chick and mouse vaccines were seen to be comparable The vaccine may be given subcutaneously in 2 doses at a week's interval, with a 3rd dose after 4 weeks

Serum Antibodies

Virucidal antibodies develop in the serum of convalescent animals, and after vaccination (Takaki, 1925, 1926 *a*, *b*, Kawamura *et al*, 1936 *a*, *b*, Hashimoto *et al*, 1936, Kudo *et al*, 1937, Kasahara *et al*, 1937 *a*, *b*, Haagen and Crodel, 1938, Smith and Reames, 1940). Antibodies, presumably due to specific infection, have been found in the sera of horses, goats, cattle, and rabbits, but not chickens, in endemic areas (Sabin, Ginder, and Matumoto, 1947)

In man, the antibody usually appears about 7 days after onset of encephalitis, but may be delayed for some weeks, it persists for at least 5 years, perhaps for life (Takaki, 1926 *a*, Kawamura *et al*, 1936 *a*, *b*, Taniguchi *et al*, 1936, Kudo *et al*, 1937, Sabin, 1947 *b*).

Sabin *et al.* (1947 *b*) describe a fatal case showing very high neutralizing indices

St. Louis, bear close resemblances to one another and differ considerably from encephalitis lethargica.

RELATIONSHIP TO OTHER VIRUSES

Japanese encephalitis antisera do not neutralize the following neurotropic viruses, Levaditi's "encephalitis" virus, herpes febrilis, Koritschoner's strain, *virus fixe*, and neurovaccine (Kudo *et al*, 1937). The virus is not related to Anopheles A virus (Roca-Garciá, 1944), Bunyamwera virus (Smithburn, Haddow, and Mahaffy, 1946), or Colorado tick fever virus (Koprowski and Cox, 1947). The finding by Webster (1938), that sheep are susceptible, introduces the question of relationship to louping ill, and therefore to the related virus of Russian encephalitis. This question is fully discussed in Ch. XCVIII, where it is shown that although Russian observers claim that Russian and louping ill viruses are related to the Japanese subgroup, Casals does not agree.

CHAPTER XCV

THE EQUINE ENCEPHALOMYELITIS GROUP OF VIRUSES. INTRODUCTORY

THERE is a number of viruses that cause encephalomyelitis in horses and mules In Europe, the infection is usually known as Borna disease, due to a serologically distinctive virus (see Howitt and Meyer, 1934)[1]; this virus is not thought to attack man, and will not be further discussed.

Another variety of equine encephalitis occurs in Russia, this virus is also antigenically distinctive (Howitt, 1935, 1937 *b*).

The equine encephalomyelitis viruses with which we shall be concerned all occur in the Western Hemisphere, and are as follows· North American equine encephalomy[illegible] types, the eastern and [illegible] virus, and the Venezue[illegible] and is described in Chapter XCVII

We shall now discuss the interrelationships of the eastern and western types of virus, the Brazilian and the Argentine viruses

Antigenic Relationship between Eastern and Western Types

The biological properties of the two North American types are closely similar, but the eastern type induces a more severe disease in horses and men

Numerous observations have been made on the antigenic relationships of the 2 strains, and it appears quite justifiable to refer to them as distinct eastern and western types of one North American virus Sharing of group antigens between the two types is best brought out by the complement fixation test (Howitt, 1938 *b*, Havens *et al*, 1943)

Cross reactions can be shown under certain conditions by the virus neutralization technique, especially if hyperimmune sera are employed (Howitt, 1938 *b*).

In general, the most satisfactory technique for "typing" strains, to elicit the maximum difference in antigenic composition, is to make use of cross resistance tests Such tests are frequently performed in guinea-pigs, and these animals when immunized to one type are usually fully susceptible to the other (see, e g, Records and Vawter, 1935), even so, some cross resistance may be demonstrable (Howitt, 1935) In immunized horses, the types prove specific, and can be differentiated, but on occasion cross resistance may be demonstrable (Records and Vawter, 1934 *b*, 1935, Shahan and Giltner, 1935 *a*, Shahan *et al*, 1942). Mice may be used in typing tests, and specificity has been demonstrated by the use of unweaned baby animals (Wright, 1942, Lennette and Koprowski, 1945)

Antigenic Structure of Strains of North American Virus

Although no considerable series of tests has been reported, observations do not suggest that there is any antigenic heterogeneity in western or in eastern strains (Ten Broeck and Merrill, 1933, Howitt, 1935, Beck and Wyckoff, 1938, Olitsky, Morgan, and Schlesinger, 1945).

The Brazilian Strain of Virus

A virus isolated from equine encephalomyelitis in Brazil has been found to be a strain closely resembling, but not identical with, the eastern type of North American virus (Carneiro, 1937, Carneiro and Cunha, 1943).

CHAPTER XCVI

NORTH AMERICAN EQUINE ENCEPHALOMYELITIS: EASTERN AND WESTERN TYPES

During the last few years, equine encephalomyelitis has developed into the major problem of the horse industry in North America, and there have been hundreds of thousands of equine deaths.

There are two antigenically distinct varieties of the North American equine encephalomyelitis virus. The western type was first isolated by Meyer, Haring, and Howitt (1931) and the eastern by Ten Broeck and Merrill (1933) and Giltner and Shahan (1933 *a*).

SOME FEATURES OF THE DISEASE IN EQUINES

Incidence

The infection (western type) was prevalent in California in 1930–31 (Meyer, 1933 *b*) In 1933 the eastern type of virus was prevalent in Virginia, Delaware, and Maryland (Giltner and Shahan, 1933 *a, c*).

Miller (1945) gives the following figures for the number of cases since 1935

1935	23,512	1940	16,941
1936	3,929	1941	36,872
1937	173,889	1942	4,939
1938	184,662	1943	4,768
1939	8,008	1944	19,590

In 1945 there were 3,212 cases (Simms, 1946)

The marked reduction in 1939 is ascribed partly to an increased resistance induced by earlier attacks, but more especially to the introduction and vigorous adoption of a policy of vaccination, using chiefly formolized chick embryo vaccine (*Public Health Reports*, 1940, 55, 601).

Fatality

The fatality rate for infection due to the eastern virus is about 90 per cent, and for that due to the western virus about 27 per cent (see, e g, Giltner and Shahan, 1933 *a*, *Public Health Reports*, 1940, 55, 601).

Geographical Distribution

The United States.

Until 1939, the Appalachian Mountains served as a barrier between the area on the Pacific side where infection was due to the western type, and the Atlantic area where the eastern type was found However, in the last few years, there has been a westward spread of the eastern type.

The western type of virus has been identified in the following states as the cause of equine epizootics (Mohler, 1943).

The Argentine Strain of Virus

Equine encephalomyelitis occurs in the Argentine, and, strangely, the virus has been found to be closely related to the western North American type, it may be regarded as a strain of the western type (Meyer *et al*, 1934; Rosenbusch, 1934, Howitt, 1935). This virus has biological properties characteristic of the equine encephalomyelitis group, and, for example, infects many animals such as rabbits, guinea-pigs, dogs, cats, rats, mice, goats, hedgehogs, pigeons, storks, geese, ducks, hawks and blackbirds, the cranial route is usually used, but in some cases a peripheral route secures infection (Rosenbusch, 1934, Remlinger and Bailly, 1935 *a, b*, 1936 *a, b, d*). Other properties are also characteristic of the group (Remlinger and Bailly, 1936 *c*).

We shall now proceed to a description of the North American equine encephalomyelitis, and after that to Venezuelan equine encephalomyelitis.

Eastern Type

Cases of human infection due to the eastern type of virus were first repor from Massachusetts and New England in 1938 (Feemster, 1938, Fothergill et 1938, Webster and Wright, 1938, Wesselhoeft, Smith, and Branch, 1938, McAd and Porter, 1939, Farber *et al*, 1940, Getting, 1941). Further cases have occur since that time in the country east of the Appalachian Mountains (see, e g, B and Irons, 1942, Hammon, 1943). In the 1938 outbreak, the disease was freq in children, and ran a severe course (Farber *et al*, 1940, Getting, 1941). T showed fever, vomited, and became drowsy. Shortly, localized twitchings, aph diplopia, paralyses, and general tonic or clonic convulsions occurred Nerv sequelae were recorded

DIFFERENTIAL DIAGNOSIS

Clinically it is difficult to distinguish between equine encephalitis and infect due to the St. Louis virus, as has been emphasized by various authors (Buss Howitt, 1941, Hammon, 1943; Eklund, 1946) Epidemics may occur in the s area and at the same time. In fact, double infections may occur in the one pati

Abortive poliomyelitis presents clinical features similar to those of mild subcl cal encephalitis, and confusion may arise in the absence of adequate laborat tests (Buss and Howitt, 1941; Adamson and Dubo, 1942 *a*, *b*, Jackson, 1942). Minnesota, Eklund (1946) drew attention to the coexistence of poliomyelitis encephalitis Useful distinctions were that 67 per cent of poliomyelitis cases curred after August 23rd, but only 6 per cent of encephalitis cases. Poliomye occurred mostly under 20 years of age

LABORATORY INFECTIONS

A few laboratory infections due to the western virus have been repor (Fothergill, Holden, and Wyckoff, 1939, Helwig, 1940).

In these cases it is probable that the portal of entry has been the respirat tract.

DISTRIBUTION OF THE VIRUS IN MAN

Virus can be recovered from the brain and cord of fatal cases The west virus has been found in the CSF (Fothergill, Holden, and Wyckoff, 1939, Ch and Norris, 1942, Gwatkin and Moynihan, 1943) As regards the blood, Ho (1939 *a*) recovered the western type from serum

CLINICAL PATHOLOGY

The CSF in the western infection shows pleocytosis, up to some hundreds cells per c mm Polymorphs are found in the first few days, but are later repla by

and

and

show a moderate polymorph leukocytosis

PATHOLOGY

Eastern Type

The pathology has been described by Fothergill *et al.* (1938), Eklund Blumstein (1938), and Farber *et al* (1940), but chiefly by Wesselhoeft, Smith, Branch (1938) The following account is mainly that of the last-mentioned auth

Brain With the naked eye, the meningeal vessels were seen to be congest especially overlying the brain stem, on section the brain was pinkish and s

Alabama	Iowa	Nevada
Arizona	Kansas	North Dakota
California	Kentucky	South Dakota
Colorado	Michigan	Texas
Idaho	Minnesota	Utah
Illinois	*Montana*	*Washington*

The eastern type of virus has been identified in the following states as the cause of equine epizootics (Mohler, 1943):

Alabama	Georgia	N Carolina
Connecticut	Massachusetts	S. Carolina
Delaware	Michigan	Texas
Florida	New Jersey	Virginia

In addition, Miller (1945) records the isolation of this type in Missouri, and it has been found in Panama (Kelser, 1937 *b*).

It will be observed that in the States of Alabama, Michigan, and Texas both types of virus have been described (see also, Randall and Eichhorn, 1941, Shahan and Giltner, 1943, Brown, 1947 *b*).

Canada.

Despite the proximity to America, the infection has not presented such a problem, although outbreaks of the disease, some serious, have been described from time to time, e.g, *Western type:* 1936, 1937, Saskatchewan (Fulton, 1938), 1938, Saskatchewan, where over 15,000 animals died (Fulton, 1941, Gareau, 1941), Ontario (Schofield and Potter, 1938), 1941, Manitoba (Bowman, 1945, see also Savage, 1942) *Eastern type.* 1938, Ontario (Schofield and Labzoffsky, 1938).

NORTH AMERICAN EQUINE ENCEPHALOMYELITIS IN MAN: CLINICAL FEATURES

Western Type

Meyer (1932, 1933 *a*) described the first cases in man. In California, many more cases have been reported since 1937 (Howitt, 1938 *a*, 1939 *a*, *b*, 1942, Buss and Howitt, 1941) In 1937 and 1938 a few cases occurred in Minnesota (Eklund and Blumstein, 1938), 800 cases were reported in 1941 (Eklund, 1946) Other outbreaks have occurred as follows Arizona (Meiklejohn and Hammon, 1942), N Dakota (Breslich, Rowe, and Lehman, 1939), Texas (Wheeler, 1941, Hammon, 1943, Sulkin, 1946) Leake (1941) referred to outbreaks in N and S Dakota, Minnesota, Manitoba, Montana, and Nebraska There have been many cases reported from the Canadian Prairie Provinces, especially in 1941 (Fulton, 1941, Gareau, 1941, Adamson and Dubo, 1942 *a*, *b*, Cameron, 1942, Davison, 1942, Donovan and Bowman, 1942 *a*, *b*, Jackson, 1942, 1943, McGugan, 1942, Norris, 1946) There was an *outbreak in 1947 in Manitoba (Bowman, 1947)*

The onset is sudden, with headache, sweating, disturbance of sleep, confusion, and drowsiness Pain and stiffness in the neck and back may occur There may be nystagmus, tremors, and paralyses The illness lasts for a week or so Spastic paralysis has been recorded as a sequel, especially in infants Davis (1940 *a*) described cerebral atrophy, mental deterioration, blindness, deafness, speech defect, and partial hemiplegia. Nineteen cases in infants were described by Medovy (1942), 6 showing sequelae Later (1943) he described further cases. Sequlae have also been described by Platou (1940) The mortality is about 10 per cent.

Mild subclinical cases of encephalitis resemble abortive poliomyelitis (Adamson and Dubo, 1942 *a*, *b*).

districts (Fulton, 1941; Richter, 1942), or from desert or mountainous country (Buss and Howitt, 1941). There is not usually any close connection between sick horses and human cases Familial cases are rarely encountered. The disease occurs from May to September, chiefly in July and August. For example, in the 1941 Minnesota outbreak, 91 3 per cent. of cases had onset between July 6 and August 23 (Eklund, 1946).

As regards the age and sex incidence, in certain outbreaks there has been a marked tendency for cases to occur predominantly in adult males Thus in 1941 in N. Dakota and Minnesota, about 70 per cent. of cases were males (Leake, 1941, Eklund, 1946) Infants seem also to be frequently attacked (Buss and Howitt, 1941; Jackson, 1943). Hammon (1943) concludes that age and sex incidence varies in different areas, regardless of which virus is concerned He points out that environmental factors of exposure strongly influence age and sex incidence.

The Rôle of Mosquitoes

The seasonal incidence of the disease suggests that an insect vector is concerned, and, following numerous investigations, this suggestion has been abundantly confirmed

The methods used in the study of the part played by mosquitoes include isolation of virus from pools of trapped mosquitoes, and transmission of the disease from animal to animal by artificially infected mosquitoes

In assessing the importance of any one species, one must pay attention to its abundance, feeding habits (which can be investigated by precipitin tests on blood meals), range of flight, and breeding place.

It is particularly important to know the feeding habits of mosquitoes, for example *Aedes* prefer mammalian to avian blood, whereas *Culex* feed on birds and mammals (see Bang and Reeves, 1942, *California Mosquito Control Association*, 1942). However, Aedes may sometimes feed on chickens (Hammon and Reeves, 1947).

The technical details of mosquito transmission experiments, and of the isolation of virus from pools of mosquitoes have been described (Knowlton and Rowe, 1935, Kelser, 1940*a*, Hammon, Reeves, and Izumi, 1942, Reeves and Hammon, 1942)

Recovery of Virus in Nature

Virus has been recovered from pools of trapped mosquitoes in endemic areas, for example from *Aedes dorsalis*, western virus (Hammon, Reeves, and Galindo, 1945*a*, and see San Joaquin Valley), *Anopheles maculipennis freeborni*, western virus (Hammon *et al*, 1945), *Culex pipiens*, western virus (Hammon *et al*, 1945), *Culex restuans*, western virus (Norris, 1946), *Culex stigmatosoma*, western virus (see San Joaquin Valley), *Culex tarsalis*, western virus (Hammon, Reeves, and Galindo, 1945*b*, Hammon and Reeves, 1947, McLintock, 1947, and see Yakima Valley and San Joaquin Valley), *Culiseta inornata*, western virus (Hammon *et al*, 1945)

Virus has been recovered from *Culex tarsalis* on no less than 75 occasions (see Hammon and Reeves, 1945) Hammon and his associates have tested over 25,000 *Aedes mosquitoes*, but have isolated the western virus only twice, i.e., 1 12,500, (see Hammon and Reeves, 1945) In contrast, the rate for all *Culex tarsalis* tested during a 3-year period was 1 225 It is of interest to note that a high infection rate of *C tarsalis* is not necessarily concurrent with a high attack rate in man (Hammon and Reeves, 1947)

Experimental Transmission Experiments

Various mosquitoes have been shown experimentally to be capable of transferring infection from an infected animal or virus suspension to a healthy animal by bite; guinea-pigs and fowls have been much used in this type of work. The

Microscopically, the subarachnoid space was infiltrated with lymphocytes and some mononuclears and polymorphs, embedded in a fibrinous coagulum.

Perivascular cuffing with lymphocytes, polymorphs, or mononuclears was a prominent feature, some plasma cells also occurring, there were some perivascular hemorrhages. *Polymorphs often infiltrated the walls of the vessels, and filled the* perivascular spaces.

Diffuse infiltrations were found most markedly in the severer cases, in the cortex, basal ganglia, pons, and down to the level of the cervical cord. The infiltrating cells were mainly polymorphs, but some lymphocytes and mononuclears also occurred.

Nerve cell degeneration was a characteristic feature, and all stages up to slight neuronophagia might be seen. Lesions were seen in the medial lemniscus, transverse fibers, and the nuclei of the pons and cranial nerves, rarely was there degeneration of the Purkinje cells.

Cord. Lesions in the cord were less pronounced than in the brain. Meningeal and diffuse cellular infiltrations were found; there was also nerve cell degeneration, especially in the cervical cord.

The changes were those of an acute disseminated encephalomyelitis pronounced in the basal ganglia, pons, and medulla. The reactions were more severe than occur in Japanese or St. Louis encephalitis, and did not resemble encephalitis lethargica or postvaccinal encephalitis

Other organs. Fothergill *et al.* (1938) reported the presence of an early interstitial pneumonitis Wesselhoeft, Smith, and Branch found general hyperemia of the abdominal and thoracic viscera, anasarca, and toxic appearances in the kidneys, spleen, and liver, there was also enlargement of the lymph glands.

Western Type

The pathological features have been described by Baker and Noran (1942), Peers (1942), Quong (1942), and Noran (1944). The meninges were found to be edematous and showed a mild mononuclear infiltration. Perivascular cuffing was with round and microglial cells, although polymorphs might occur The lesions in the brain and cord were characteristically small and focal Petechial hemorrhages and areas of demyelination were seen in some cases Peers refers to the fact that the majority of infiltrating cells is mononuclear, in contrast to the predominance of polymorphs described in eastern infections Noran refers to chronic changes such as cystic degeneration of the left frontal and temporal lobes, parenchymal degeneration, and focal areas of inflammatory infiltration. Many vessels were occluded by endothelial proliferation and calcium deposits.

LABORATORY DIAGNOSIS

In fatal cases, brain and cord suspension is inoculated cerebrally in mice and guinea-pigs To "type" the strain, inoculation is made in guinea-pigs immunized against the western or eastern type separately In other cases, inoculation of CSF is made, but the virus is not uniformly present The inoculation of the chick embryo has been specially recommended (Fulton, 1941)

Main reliance is placed on the virus neutralization or complement fixation test carried out with acute and convalescent phase sera (Jakmauh and Feemster, 1939, Buss and Howitt, 1941, Adamson and Dubo, 1942 *a*, *b*, Casals, 1941, 1945 *b*, Gold and Hampil, 1942, see also Ch XI)

EPIDEMIOLOGY

Incidence

Epidemic equine encephalomyelitis in man is predominantly a disease of the countryside, especially farming areas It has only rarely been reported from urban

infection is transmitted between these animals largely by mosquitoes, and to a lesser degree by mites and ticks

The evidence supporting the rôle of animal reservoirs is as follows

The eastern virus has been recovered from pheasants (Tyzzer, Sellards, and Bennett, 1938, Van Roekel and Clarke, 1939, Beaudette, Black, and Hudson, 1941, Sellards, Tyzzer, and Bennett, 1941); and from pigeons (Fothergill and Dingle, 1938). The sera of various wild fowl have been found to neutralize the virus (Brown, 1947 *b*), and it has been shown that sparrows and pigeons can be infected by the bite of an infected mosquito, infected birds can serve as a source of infection for mosquitoes (Davis, 1940 *b*) As regards the western virus, the observations of Hammon and his associates, mainly on the Pacific coast of America, chiefly by means of serum tests, have pointed to infection of mammals and birds (especially fowls) with this and the St. Louis virus (Hammon *et al.*, 1941 *a*, Howitt and van Herick, 1941, 1942; Hammon and Reeves, 1943, 1947) Hammon and Reeves (1946) showed that viremia was readily produced in chickens inoculated subcutaneously. The virus may be spread between chickens by mosquitoes, especially *Culex tarsalis*, and these infected mosquitoes may also bite horses and men The virus may also be spread from chicken to chicken by the chicken mite *Dermanyssus gallinae* (Sulkin, 1945).

The western virus has also been recovered from the naturally infected prairie chicken *Tympanuchus cupido americanus* Reichenbach (Cox, Jellison, and Hughes, 1941), and from a pig (McNutt and Packer, 1943) Some evidence has been produced that gophers (*Citellus richardsoni*) may be infected (Gwatkin and Moore, 1940, Gwatkin and Moynihan, 1942). Serological tests do not suggest that wild rodents and rabbits play much part, but antibodies to the California virus are not uncommon (Hammon and Reeves, 1947).

It is evident, therefore, that the virus of equine encephalitis is widely distributed in nature. Infected animals show a short period of viremia, and during this phase mosquitoes may become infected.

Owing to the probable short duration of the viremia in animals, it would appear that the main "reservoir" of the virus must be in mosquitoes, and that the virus may survive in them from one season to the next It is possible that ticks or mites serve as reservoirs of infection for animals, especially fowls Although in certain areas the evidence incriminating the fowl is strong, in other districts, for example in Nebraska and Texas, there is less certainty, and other hosts may be concerned

MOSQUITO TRANSMISSION IN CERTAIN LOCALITIES IN NORTH AMERICA

A. Western Districts

1 Yakima Valley.

Hammon and his associates have made detailed studies in this locality in the State of Washington, where there has been a number of outbreaks of human encephalitis due to the St Louis virus and to the western virus, and in some cases there has been a double infection (Hammon, 1941, 1943, Hammon and Howitt, 1942, Hammon *et al.*, 1945) Encephalitis has also been noted in equines

The human cases have occurred mainly in or near orchards The onset has been in July, reaching a peak in August, and then rapidly declining

Hammon and Reeves (1947) give the following as the number of clinically recognized human cases of encephalitis, 1938, 4, 1939, 31, 1940, 58, 1941, 26, 1942, 28, 1943, 1, and 1944, 0.

The conditions in this hot irrigated valley are specially favorable for mosquitoes, and the seasonal incidence pointed to their part in the spread In support, western virus (and St Louis virus) has been isolated from pools of *Culex tarsalis* mosquitoes

following have been shown capable of transferring the infection in this way: *Aedes aegypti*, eastern and western virus (Kelser, 1933, 1935; Merrill and Ten Broeck, 1934, 1935; Davis, 1940 *b*); *Aedes albopictus*, western virus (Simmons, Reynolds, and Cornell, 1936), *Aedes atropalpus*, eastern virus (Davis, 1940 *b*); *Aedes cantator*, eastern virus (Merrill, Lacaillade, and Ten Broeck, 1934); *Aedes dorsalis*, western virus (Herms, 1933, Madsen and Knowlton, 1935), *Aedes lateralis*, western virus (Reeves, 1941); *Aedes nigromaculis*, western virus (Madsen and Knowlton, 1935), *Aedes sollicitans*, both types (Merrill, Lacaillade, and Ten Broeck, 1934); *Aedes sylvestris*, western virus (Merrill, 1933), *Aedes taeniorhynchus*, western virus (Merrill, 1933, Kelser, 1937 *a*, 1938); *Aedes triseriatus*, eastern virus (Davis, 1940 *b*), *Aedes vexans*, eastern and western virus (Knowlton and Rowe, 1935; Davis, 1940 *b*); *Culex tarsalis*, western virus (Hammon and Reeves, 1943; Hammon, Reeves, and Gray, 1943); *Culiseta incidens*, western virus (Hammon and Reeves, 1943), *Culiseta inornata*, western virus (Hammon and Reeves, 1943).

Hammon and Reeves (1945) quote Japanese workers as having reported transmission of the western virus with *Culex pipiens* var. *pallens*, and *Armigeres obturbans*. The same workers claim to have transmitted the eastern virus by *Culex pipiens* var *pallens*, and *Culex tritaeniorhynchus*

A number of workers has adduced evidence that encephalomyelitis viruses proliferate in the tissues of the following mosquitoes, and increase in amount up to ten thousand fold *A sollicitans*, *A. aegypti* (Merrill, Lacaillade, and Ten Broeck, 1934, Merrill and Ten Broeck, 1934).

The virus appears to be well distributed through the tissues of the infected mosquito

It has been found that the western virus increases in titer when cultured in the presence of mosquito tissues (Trager, 1938)

The mosquito probably becomes infective about 7–20 days after the infecting meal, at a suitable temperature, and remains so for the rest of its life, transovarial infection apparently does not occur (Merrill, Lacaillade, and Ten Broeck, 1934; Merrill and Ten Broeck, 1935)

Probably because the titer of virus in the blood of the horse is so low, and the period of viremia short, no one has succeeded in infecting a mosquito by allowing it to bite a horse

THE RÔLE OF OTHER ARTHROPODS

Ticks have been incriminated Thus, the western virus can be passed hereditarily in *Dermacentor andersoni* Stiles (Syverton and Berry, 1941 *b*), larvae nymphs, and adults can all infect by feeding These ticks became infected after feeding on a gopher (Gwatkin, 1939).

The western virus has been isolated from *Triatoma sanguisuga* Le Conte gathered in Kansas, this tick feeds largely on vertebrates (Kitselman and Grundmann, 1940). It can transmit virus experimentally in guinea-pigs (Grundmann *et al*, 1943) Experiments of these workers did not suggest that *D. variabilis* Say (the dog tick) is of importance as a transmitter of infection

Mites have also been shown capable of transmitting the infection Thus western virus has been recovered from mites *Liponyssus sylviarum* from the nest of a blackbird in Kern County, California, from the nest of an English sparrow, virus was recovered from this mite and from *Dermanyssus americanus* Ewing (Reeves *et al*, 1947). The virus has also been recovered from the chicken mite *Dermanyssus gallinae* (Sulkin, 1945), but studies in Yakima have proved negative (Hammon and Reeves, 1947)

Animal Reservoirs of Infection

There is definite evidence that the virus of equine encephalomyelitis infects not only equines and man, but many domestic and wild animals It is probable that

species They drew attention to the influence of altitude on the distribution of the disease by its effect on limiting the flight of the probable vector *C. tarsalis*

B. Eastern Districts

1. Massachusetts.

In the 1938 outbreak, it was concluded that *Aedes vexans* was the most likely vector, *A. sollicitans*, and *A. cantator* may have been partly responsible (Getting, 1941; Feemster and Getting, 1941). Davis (1940 *b*) found that the following mosquitoes native to Massachusetts could transmit the eastern virus from infected animals to others experimentally. *A. vexans, A. sollicitans, A cantator, A. atropalpus,* and *A triseriatus*. In addition, a laboratory-reared *A. aegypti* could transmit the infection. *Culex, Mansonia,* and *Anopheles* gave negative results. He also concluded that *A vexans* was the main vector.

2. Oklahoma.

carry out investigations in dry farming areas, and an opportunity occurred in Pontotoc County, Oklahoma, where in September and early October there was an extensive outbreak of encephalitis in horses (Reeves, Mack, and Hammon, 1947). Because it was late in the season when the survey began, arthropod collections were small No virus was isolated from mosquitoes, horn flies, or chicken mites. Sera were obtained from wild and domestic animals on farms where equine encephalitis occurred. Only 15 out of 104 sera tested had antibodies to the western encephalitis virus, and 9 of these were from horses recovering from encephalitis, 8 out of 70 sera tested for St Louis virus were positive. Of chickens tested, only 2 out of 27 had neutralizing antibodies to the western virus, and none out of 22 to St. Louis virus

vectors

been ir

suga),

(*Dermanyssus gallinae*). Knowledge regarding vertebrate hosts is no more complete This report emphasizes the apparent differences between the epidemiology of these infections in the Far West and the dry farming areas of the East. In the latter areas, it may well be that the virus is adapted to a reservoir host other than birds, and that arthropods other than *C. tarsalis* are of importance.

PROPERTIES OF THE VIRUS

Physicochemical Properties

Size Experiments with Elford's collodion membranes have estimated the virus to be very small, probably from 20–35 mμ (Bauer, Cox, and Olitsky, 1935; Lazarus and Howitt, 1937, Tang, Elford, and Galloway, 1937). Calculations by Elford's centrifugation technique have confirmed these figures (Tang, Elford, and Galloway, 1937)

the electron microscope The easte ... -47 mμ (Taylor *et al.*, 1942 *a*, Shar ... or disk-shaped, and measures abo

in

194

cause maturation (McLimans, 1947).

on about 50 occasions. *Culex pipiens*, *Anopheles maculipennis freeborni*, and *Culiseta inornata* have also been found infected (Hammon *et al.*, 1941 *b*, 1942 *a*, *b*, 1945, Hammon and Reeves, 1945, 1947). There is little doubt that *Culex tarsalis* is the most important vector of equine and St. Louis encephalitis in the Yakima Valley This mosquito has been shown to feed frequently on domestic fowl and other animals and man. The feeding habits of this mosquito alone can explain the incidence of encephalitis and the distribution of antibodies in man and animals (Reeves and Hammon, 1944). Nevertheless, in 1944, when there were no cases of human encephalitis, the infection rate of *Culex tarsalis* with western virus was very high (Hammon and Reeves, 1947).

With regard to the feeding habits of possible mosquito vectors, it was found that western and St Louis viruses were neutralized by about 50 per cent. of sera from domestic fowl, by 20 per cent of sera from wild birds, by 35 per cent. of sera from horses, cows, goats, pigs, mules, and dogs; less commonly did the sera of wild mammals neutralize the virus (Hammon *et al.*, 1942 *c*, 1945).

These workers therefo[illegible] rary reservoirs f[illegible] in horses than [illegible] that a large proportion of horses becomes immune, the horse epizootic expends itself some weeks before the outbreak in man

The rôle of domestic fowls has been further strengthened by the finding that they develop viremia when suffering from an inapparent infection (Hammon, 1943), and that mosquitoes can transmit virus from fowl to fowl.

2. San Joaquin Valley.

Hammon, Reeves, and Galindo (1945 *a*) studied the epidemiology in this valley in Kern County, California, in 1943. They identified 19 cases of western infection and 5 cases of St. Louis encephalitis in man Over 10,000 blood-sucking arthropods were tested, and 31 strains of western virus were isolated, 28 strains of western virus were isolated from C. *tarsalis*, 2 from *Aedes dorsalis*, and 1 from *Culex stigmatosoma*. It was found that 55 per cent. of all C. *tarsalis* had engorged on birds, and chickens showed neutralizing antibodies to the western equine and St. Louis viruses. They concluded that in California, as in Yakima, *C. tarsalis* is the main vector. Some 622 C *tarsalis* caught in the winter yielded no virus.

A later paper (Hammon and Reeves, 1947) refers to 1943 as well as 1944; in the latter year there were only 2 human infections due to western and 3 to St Louis virus From 2,494 *Culex tarsalis* tested in 1944 one strain of western and one strain of California virus was isolated, from 4,425 *Aedes dorsalis* one strain of St Louis and one of California virus was isolated, these rates were very low compared to 1933. Again, chicken sera were found to neutralize western and St Louis viruses.

3. Canada.

In Manitoba in 1944 one strain of western virus was recovered from a pool of *Culex restuans* (Norris, 1946) Virus has also been found in *C. tarsalis* (McLintock, 1947).

4. Texas.

In the Lower Rio Grande Valley, Hammon, Reeves, and Irons (1944) could not isolate virus from 19 species of mosquito Antibodies were rare in the sera of horses and chickens.

5. Colorado.

Black, Absher, and McDonald (1945) investigated the mosquito situation in 1943–4 They found *C tarsalis*, *C pipiens*, and *Mansonia perturbans* the common

Eggs

Eggs can be infected by any route of inoculation, virus generalizing and killing

flammatory changes, thrombosis, and hemorrhage, appear a few hours after inoculation. The membrane becomes thickened and opaque The virus generalizes and invades the embryo, which dies after 16–24 hours, it is found in the amniotic fluid and blood (Covell, 1934, Higbie and Howitt, 1935; Bang, 1943). Multiplication begins 3 hours after inoculation, and reaches the maximum titer at 16–24 hours (Bang, 1943). Covell (1934) found acidophilic inclusions in the nuclei of the nerve cells in the brain, with some necrosis.

Virus-serum mixtures can be titrated on the membrane (Higbie and Howitt, 1935). The membrane can also be used in virus isolation work. Virus suspensions can also be titrated after inoculation on the membrane, using 50 per cent. embryo mortality end points (Bang, 1943).

It has been shown that the resistance of the embryo increases with increasing age, in older embryos death is delayed and the virus titers are lower (Bang, 1943)

Duffy (1944) has shown that the western virus grows only poorly if injected into embryos in which St. Louis virus has been previously inoculated.

The yolk sac route has been used (Cox, 1939, Stimpert, 1939). In these laboratories, Crawley has made extensive use of this route. Virus invades, and produces death of the embryo within 24 hours Virus suspensions and virus-serum mixtures can be titrated by this route, death of the embryo being taken as the end point (1948).

With the western strain, no evidence was obtained that serial egg passage altered antigenic structure (Shahan and Eichhorn, 1941).

Inoculation of the embryonated egg is widely used in the preparation of formolized vaccine from embryonic tissue (see p. 1131). Beard and coworkers have prepared purified virus from infected embryonic tissue (see above)

EXPERIMENTAL INFECTION OF ANIMALS

Horses

Horses can be infected by cerebral inoculation with either type In addition, the eastern virus infects by the intravenous and intracutaneous routes (Meyer, 1933 *b*, Meyer *et al*, 1934)

Infected horses show the following phases of illness (Ten Broeck, Hurst, and Traub, 1935, Mitchell, Walker, and McKercher, 1938) (1) there is an early stage of fever with viremia, (2) the animals then become hypersensitive, (3) tremors, neck rigidity, and slight lethargy are noted, (4) finally there is marked lethargy, tetanoid spasms, and Cheyne-Stokes breathing

The pathological changes in horses have been studied by Meyer (1933 *b*) and Hurst (1934) The changes, which are more intense and extensive with the eastern strain, are those of a primary nerve cell degeneration, with leukocytic infiltration Inclusions like those of Borna disease may be seen in the nuclei

Other Domestic Animals

The following are susceptible *goats*, either type (Meyer *et al*, 1934; Shahan, Giltner, and Schoening, 1939), *calves*, both types (Giltner and Shahan, 1933 *b*, Hurst, 1934, Shahan, Giltner, and Schoening, 1939), *sheep*, eastern virus (Hurst, 1934, Shahan, Giltner, and Schoening, 1939), *pigs*, both types (Shahan, Giltner, and Schoening, 1939), *dogs*, both types (Hurst, 1934, Shahan, Giltner, and Schoening, 1939, Howitt, 1940, Schlotthauer, 1941).

Infectivity (western virus) is said to be preserved in 50 per cent. glycerol (Howitt, 1934 *b*), or by rapid complete drying *in vacuo* over phosphorus pentoxide and storage *in vacuo* (Shahan and Eichhorn, 1941). Infectivity is well preserved in glass vials kept in the dry icebox.

Purified eastern virus is most stable at pH 7–10 (Finkelstein *et al.*, 1940).

Miscellaneous. Brain tissue infected with western virus shows metabolic differences from tissue infected with poliomyelitis (Nickle and Kabat, 1944). The western virus depresses the rate of anaerobic glycolysis of embryonic tissues (Victor and Huang, 1944). Rosenow claims to have isolated virus from streptococci (1942, Rosenow and Caldwell, 1941)

The Chemical Nature of Encephalomyelitis Virus

Wyckoff (1937) carried out ultracentrifugal analysis of infected tissue, and isolated a heavy protein-like component Later studies of an exhaustive nature, that can only be briefly summarized as follows, have been carried out by Beard and his associates (Finkelstein *et al.*, 1938; Sharp *et al*, 1939 *a*, *b*, 1940 *a*, *b*, 1943; Taylor *et al*, 1939, 1940 *a*, *b*, 1941 *a*, *b*, 1942 *b*, 1943; Taylor, Sharp, and Beard, 1940, see also *Ch. VII*).

1. They have worked with infected chick embryo tissue, and have purified the contained virus by ultracentrifugation.

2. A macromolecular infectious component has been isolated from infected embryos (both types of infection). The S_{20} of the eastern virus is 273×10^{-13}, and of the western virus 265.5×10^{-13}. Calculations of size give 50 4 mμ (eastern) and 56 8 mμ (western). These heavy components are most stable at pH 7–8 5. They are inactivated by ultraviolet light They behave as virus in infectivity experiments The infectious unit of eastern virus was thought to represent 250 molecules. The virus is a complex of high molecular weight, and contains phospholipids, cholesterol, fatty acid, and ribonucleoprotein.

3 Suitably purified chick embryo vaccines have been prepared, eliminating most of the unwanted protein material

4 A macromolecular lipoprotein complex containing 10 5 per cent ribonucleic acid can be isolated from normal embryos. It has a S_{20} of 78.7×10^{-13}, a molecular weight of 4,800,000, and a particle diameter of about 23 mμ A similar component in infected embryo tissue is unrelated to the virus

It may here be mentioned that another group of workers has found highly purified preparations of eastern virus to contain up to 77 per cent of components antigenically related to normal tissue components (Engel and Randall, 1947 *b*)

Reaction to Physical and Chemical Agents

Only a few special observations will be mentioned, the virus being fairly readily destroyed by physical and chemical agents Thus, Kempf *et al* (1945) found that the eastern virus was inactivated by a chlorine concentration of 0.71 p p m Both types are destroyed by ether (Birch, 1941, Sulkin and Zarafonetis, 1947) Mustard was found to inactivate the eastern virus, antigenicity being retained (Ten Broeck and Herriott, 1946) Aspergillic acid has no effect *in vivo* or *in vitro* on the infectivity of the western virus (Sulkin and Goth, 1945) Penicillin is ineffective in tissue cultures or eggs (Parker and Diefendorf, 1944)

Tissue Cultivation

The western virus has been cultivated in tissue culture (Olitsky, Cox, and Syverton, 1934, Zinsser and Schoenbach, 1937, Sanders and Molloy, 1940, Huang, 1943 *a*, Sanders and Huang, 1944) The eastern virus has also been cultivated (Cox, 1936)

creasing age a gradual decrease in susceptibility to infection by the peritoneal route, with increasing age there was a prolongation of the incubation period in those that did succumb. In young mice, virus was recovered in large amounts from the blood, but in adults only small amounts were found Lennette and Koprowski made similar observations with both strains They found that 3-day mice were susceptible to subcutaneous injection, intraperitoneally, mice up to 14 days of age were susceptible. In practice, age does not influence susceptibility to cerebral injection

Mice suffering from infection with the western virus were found to be more susceptible than usual to the dehydrating effect of intraperitoneal glucose (Hoyt, Holden, and Rawson, 1939) An intraperitoneal, intramuscular, or intravenous injection of glycerin or concentrated salt enhanced the activity of eastern virus injected intramuscularly, apparently due to dehydration (King, 1940 *a*, 1942) Etherization after exposure has been reported as exerting a beneficial effect on the course of western infection in mice, the effect on eastern infection being less marked (Sulkin, Zarafonetis, and Goth, 1945, 1946).

The pathogenesis of the infection has been studied after various routes of inoculation. After nasal inoculation (eastern virus) it appears that virus spreads by the olfactory nerves to the brain (Sabin, 1938)

After peritoneal inoculation in young mice, virus invades the blood (Olitsky, and Harford, 1938 *b*, Morgan, 1941), and probably reaches the CNS by being excreted in the nasal mucosa and then passing by the olfactory route

Sabin and Olitsky (1938 *a*) studied the effect of inoculating virus in the leg muscles With the eastern virus, in the majority of cases, virus entered the blood and passed to the brain by the olfactory paths, in a few cases, the virus spread by the nerves. With western virus in young mice, the blood and olfactory system were usually involved, in older animals spread was usually by nerve fibers

On intra-ocular injection, eastern virus was found to invade by the optic nerves (King, 1940 *c*).

[illegible]

Guinea-pigs

[illegible] the cerebral route produc[illegible] 1933 *b*) The virulence of [illegible]astern virus is the more virulent. Guinea-pigs are also susceptible by the following peripheral routes nasal, pad, ocular, muscular, peritoneal, and subcutaneous

A number of workers has investigated the pathogenesis and pathology of the infection after peripheral inoculation Thus, Howitt (1934 *a*) showed that when infected [illegible] virus [illegible] Remo[illegible] ing on nasal inoculation

Detailed studies have been carried out by Hurst (1936). After intramuscular injection, he showed that most animals infected with eastern virus developed nervous symptoms and died With the western virus, some survived and became immune He found that inapparent infections were unusual There was little evidence of local proliferation at the site of muscular inoculation, but increase was evident when eastern virus was injected in the pads

He found a phase of viremia, as in monkeys, and again virus was not found in any quantity in the viscera Multiplication of virus must have occurred in the blood or closely associated tissues After these routes of inoculation, virus was first found in the anterior brain, and not in the cord. Virus appeared to pass to the CNS indirectly from the blood, and not by direct neural paths.

Monkeys

Monkeys and apes can be infected by the cerebral and many peripheral routes, and die in a few days (Meyer, 1933 *b*, Hurst, 1936, Webster and Wright, 1938, Wyckoff and Tesar, 1939, Howitt, 1941 *b*).

Virus is found in the blood and cerebrospinal fluid. The peripheral routes used include: nasal, venous, muscular, dermal, and intralingual.

The most detailed investigations are those of Hurst (1936) who has studied the pathogenesis of the infection due to both types of virus, particularly after peripheral inoculation (i e, intradermal, intramuscular, intravenous, and intrasciatic) He has shown that the monkey exhibits 2 phases of illness. In the first, or visceral phase, virus circulates in the blood, and appears to multiply there, or in some tissue associated therewith, as no large quantity is found in the viscera. The only histological clew was afforded by the finding of occasional necrotic cells in the liver during this phase of viremia Animals inoculated peripherally may show no more than this phase. The second phase of nervous involvement may follow the visceral, *there is a rise of temperature, tremor, excitement, paralysis, or ataxia. This involvement* occurs at a time when there is a prompt antibody response, and disappearance of virus from the blood Unless there are signs of nervous involvement, recovered monkeys are not usually resistant to cerebral inoculation.

Virus may be found in the CSF before the onset of nervous symptoms. He found no evidence of neural spread after intradermal or intramuscular inoculation in the thigh, the anterior brain becoming infective before the cord The findings suggested that virus does not directly penetrate the blood brain barrier. In further support of the absence of neural spread, changes were only found late in the spinal ganglia.

Hurst (1936) found that the lesions in the nervous system of monkeys are similar to those in the horse, and appeared first at the time of rise of temperature After intradermal inoculation, there was some local cellular necrosis and inflammatory reaction.

Mice

Mice can be infected with the eastern and western viruses cerebrally and nasally. Under certain conditions, peripheral inoculation may secure infection, for example, subcutaneously, peritoneally, intramuscularly, intra-ocularly, into a nerve, in the pad, and intravenously.

Signs of illness appear in 48–72 hours, and the animals become rapidly prostrate and die shortly afterward The brain shows inflammatory and degenerative lesions (Olitsky, Cox, and Syverton, 1934) There is edema, congestion, focal hemorrhage and necrosis of Purkinje cells, and nerve cells of the motor nuclei in the brain stem and cord Intranuclear inclusions may be seen when the more chronic illness initiated by the nasal route is studied They are 1–2 μ in diameter, acidophilic, and occur in the hippocampus and anterior gray matter of the cord

The effect of age on susceptibility has been investigated (Olitsky, Cox, and Syverton, 1934, Olitsky and Harford, 1938 *a*, Sabin and Olitsky, 1938 *b*, King, 1940 *a*, *b*, Morgan, 1941, Lennette and Koprowski, 1944 *a*, *b*) Thus, Sabin and Olitsky (1938 *b*) found that with the eastern virus, 15-day mice were all susceptible by the muscular or peritoneal routes, at one month only 50 per cent could be infected, and at 3 months hardly any Resistant older animals could be infected by the sciatic nerve. With the western virus, 80–90 per cent of 15-day mice developed encephalitis after inoculation in the muscles of an extremity, at 21 days, the majority developed flaccid paralysis, and some resisted, at one month, almost all resisted Sciatic inoculation, however, produced paralysis

Infant mice are susceptible to peritoneal inoculation, but adults resist (Olitsky, Cox, and Syverton, 1934). Working with the eastern virus, Morgan found with in-

Birds

Various experiments on the infection of chickens have been referred to above (see Epidemiology). Fowls develop viremia on subcutaneous injection (Howitt, 1940, Tyzzer and Sellards, 1941)

Pigeons have been infected with the eastern virus (Giltner and Shahan, 1933 *b*; Traub and Ten Broeck, 1935, Fothergill and Dingle, 1938, Traub, 1938, Shahan, Giltner, and Schoening, 1939), and the western virus (Shahan, Giltner, and Schoening, 1939, Howitt, 1940, Graham and Levine, 1941, 1942).

Pheasants have been infected with the eastern strain (Shahan, Giltner, and Schoening, 1939, Sellards, Tyzzer, and Bennett, 1941).

The western virus can infect the duck, turkey, goose, hawk, guinea fowl, sparrow, quail, junco, thrasher, and vulture (Remlinger and Bailley, 1936 *a*, *e*, Shahan, Giltner, and Schoening, 1939, Howitt, 1940).

The burrowing or ground owl is susceptible to both types (Syverton and Berry, 1941 *a*).

ANTIGEN-ANTIBODY REACTIONS: EXPERIMENTAL CONSIDERATIONS

Virus Neutralization

Antibodies that neutralize the infectivity of virus rapidly develop in convalescence from infection in man and animals.

Antibodies also develop after the immunization of animals with formalin-inactivated virus, they may reach as high a titer as in animals vaccinated with live virus (see, e g, Cox and Olitsky, 1936 *b*, Morgan and Olitsky, 1941). Certain differences in the protective powers of sera obtained after immunization with live or formolized virus have been described (Olitsky and Harford, 1938 *c*, Olitsky and Morgan, 1939 *b*).

Working with eas [illegible] development of serum antibodies [illegible] nay be transmitted to young mic [illegible]

Ruchman (1946) [illegible] effect of diet on cerebral resistanc [illegible] isted 100–200 times as much virus cerebrally as did underfed mice. The sera of well fed mice neutralized between 10 to 100 times as much virus as did the sera of underfed animals Removal of the whole vitamin B complex from the diet produced no very definite results Deficiency of thiamin or riboflavin had no effect on the production of antibodies or cerebral resistance However, diets deficient in protein or carbohydrate lowered cerebral immunity to about 1/10 of that in controls

When serum antibody has fallen some months after the inoculation of live or formolized virus, a single dose of either type of antigen induces a greater antibody rise than occurs after the first inoculation (Morgan and Olitsky, 1941) Serum antibodies are associated with beta and gamma globulin (Koprowski, Richmond, and Moore, 1947)

Antibodies appear also in the CSF after vaccination with live or inactive virus (Howitt, 1941 *b*, Morgan, Schlesinger, and Olitsky, 1942)

Technique of tests.

Tests for virus neutralization can be carried out in various ways. A popular method involves the inoculation of serum-virus mixtures cerebrally in guinea-pigs.

A clew to the route of invasion of the CNS, after intradermal and intramuscular injection, was furnished by observations on the effect of nasal inoculation. Virus was found first in the olfactory bulbs and anterior frontal region. There was inflammatory infiltration of the bulbs and overlying meninges, and in the frontal brain meningitis, microglial proliferation, and neuronal destruction A similar distribution of lesions was sometimes found after muscular injection. He found in some cases during the period of viremia following peripheral inoculation (western) that virus could be detected in the nasal washings He suggested that in some cases at least, after intramuscular injection, the nervous system is invaded by virus which has passed from the blood into the nasal secretions.

It seems that after nasal inoculation, virus ascends via the perineural lymphatics of the olfactory nerves. After inoculation by other routes, virus may be excreted into the nasal passages, and ascend to the CNS by the olfactory route.

Peripheral routes of inoculation were also used by King (1938) with the eastern virus He found the earliest changes in the brain to take the form of a focal inflammation of the blood vessels. Before the onset of symptoms, such changes were *found irregularly in the gray matter, especially the neo- and olfactory cortices.* Neuronal destruction might also occur He found inflammatory changes to be less marked after cerebral inoculation.

He concluded (1939 *a*) that the frequency of lesions in the neocortex with intact subcortical centers rendered nerve spread improbable. Virus injected peripherally invaded the blood, and passed from there into the brain An exception was *the case of ocular injection where axonal paths of the optic nerves were involved* (1939 *b*).

Western virus transmitted serially in the pad eventually loses its neurotropic powers, and becomes dermotropic (Olitsky, Cox, and Syverton, 1934)

Guinea-pigs immunized with the western virus, and then injected cerebrally with this virus were found to be resistant to a subsequent cerebral injection of eastern virus, for about 2 weeks, or vesicular stomatitis virus for 4 days. This may be an example of the interference phenomenon, or may be due to a nonspecific neutralizing effect exerted by antibody appearing in the brain (Schlesinger, Olitsky, and Morgan, 1944).

Various Rodents

The following have been proved susceptible woodrat, both types of virus (Howitt, 1940; Grundmann *et al.*, 1943), cotton rat, both types (Howitt, 1940, Grundmann *et al*, 1943), field vole and woodchuck, both types (Syverton and Berry, 1940) [illegible] or gopher, both types (Syverton and Berry, 1936, [illegible] 40), wild mice, western virus (Howitt, 1940), rats, [illegible] chipmunks and ground hogs, western virus (Mitchell and Walker, 1941), hamsters, both types (Shahan and Creech, 1942, Watson and Smadel, 1943), hedgehog, eastern virus (Shahan, Giltner, and Schoening, 1939)

Rabbits

Rabbits can be infected cerebrally, in adult rabbits, subcutaneous injection may lead to inapparent invasion of the CNS, preceded by viremia, in young rabbits encephalitis follows subcutaneous injection (Meyer, 1933 *b*, Schlesinger, Morgan, and Olitsky, 1942).

Wild rabbits are said to be susceptible to both types (Howitt, 1940, Syverton and Berry, 1940).

If large doses of either virus are injected in the eye, corneal edema and opacity result, perhaps due to a toxic reaction (Evans and Bolin, 1946).

activated serum-treated virus suggested that aggregation occurred in the first set of conditions It appears that when serum acts on virus, both agglutination and neutralization take place. The phenomenon of "percentage neutralization" is probably dependent on aggregation (see also, Cox and Olitsky, 1936 *b*).

2 As occurs with other viruses, reactivation of neutral mixtures may occur on dilution (Pierce, Kempf, and Soule, 1941), but after prolonged contact this may not be possible (Labzoffsky, 1946 *b*).

[illegible]

vestigated (Cox and Olitsky, 1936 *b*, Olitsky and Harford, 1938 *a*; and others). Thus, incubation at 37° C. for 2½ hours did not alter the protective action of serum inoculated peritoneally in young mice (Olitsky and Harford, 1938 *a*). In work with the egg, Crawley has found that neutralization of eastern virus by antiserum occurs immediately, and is not increased by incubation

On the other hand, using western virus Morgan (1945) concluded that a reaction did occur between serum and virus on incubation at 37° C.

Making similar observations with the eastern virus, using cerebral inoculation in mice, Labzoffsky (1946 *b*) reported a progressive decrease in infectivity with increased duration of contact at 37° C.

5. If antibody does combine with virus in test tubes, the combination cannot be stable, for differing degrees of neutralization are demonstrated according as to whether the mixtures are inoculated cerebrally or peritoneally in young mice (Olitsky and Harford, 1938 *a*). In a second experiment (1938 *b*) using the passive immunity technique, they showed that this variation in protective capacity was correlated with the path followed by the virus to the CNS. When virus is inoculated peritoneally or muscularly, it invades the blood and neutralization presumably takes place there, or in some non-nervous tissue. When virus is inoculated in nerve tissue, however, little protection occurs.

6 A complement-like substance plays some part in the virus neutralization reaction. The neutralizing capacity of western virus antiserum falls off if kept at 4° C., and can be fully restored by the addition of complement. Neutralizing antibody in rabbit serum present in the pseudoglobulin fraction can be enhanced in effect by complement (Morgan, 1945). Whitman (1947) showed that the action of neutralizing antibody to western virus is augmented by the presence in normal serum of a heat-labile accessory substance This substance loses most of its activity when diluted 1/10, or when inactivated by heat, or when the serum is frozen at −20° C.

Complement Fixation

Complement fixation can be demonstrated readily between antisera and appropriate antigens

Although the complement fixing and virus neutralizing antibodies often run parallel (see, e g, Sulkin and Izumi, 1945), the fixation test may become negative while the neutralization test is still positive (Casals, 1945 *b*)

Antigens of various types have been used. Brain suspensions can be employed (Howitt, 1937 *b*) Extract prepared by alternate freezing and thawing can serve as antigen (Casals and Palacios, 1941 *a*, *c*). Irradiation of such suspensions produces a noninfective [illegible]

C

by t

Study has been made of the effect of using *young susceptible mice, injected* peripherally. Thus virus-serum mixtures given peritoneally were found to protect young mice in dilutions which induced infection by the cerebral route (Olitsky and Harford, 1938 *a*). Wright (1942) used an intraperitoneal protection test in unweaned mice. Lennette and Koprowski (1944 *b*) found that the younger the animal, the greater the amount of neutralization demonstrated. They used 3-day mice injected subcutaneously, or 8–14 day mice injected peritoneally. They showed that the cerebral route is too exacting, by comparing the results of inoculating human antiserum-virus mixtures subcutaneously in 3-day mice, and cerebrally in 28-day animals (1946). By the cerebral route, hardly any antibody was detected, but it was shown to be present in considerable amount by the subcutaneous route.

The stock of virus, to be of uniform potency, should be preserved frozen (see, e g, Hammon and Izumi, 1942)

Passive immunity.

High titer neutralizing antiserum can be produced by the immunization of *horses, rabbits, or guinea-pigs, but prolonged courses of injections are not needed*

Passive protection with serum can be shown experimentally. Thus with guinea-pigs, intravenous injection protects against a cerebral dose (Friedemann, Hollander, and Bornstein, 1944). Intracardial injection protects against an inoculation in the pad for 24–48 hours, in some cases, death is delayed (Olitsky, Schlesinger, and Morgan, 1943). Zichis and Shaughnessy (1945) also reported successful results in guinea-pigs.

Experiments of Olitsky and Harford (1938 *b*) may throw light on the mechanism involved in passive immunity in mice. They gave 12–15 day mice serum intraperitoneally, and then injected virus in the brain, nose, muscles, or abdomen Protection was only shown to the latter 2 routes of infection This is presumably because in these instances virus invades the blood and the site of neutralization is either here or in some non-nervous tissue When the pathway of the virus is in nervous tissue *from the beginning, there is little opportunity for neutralization*

As regards treatment, serum is said to arrest the infection in guinea-pigs and mice (Zichis and Shaughnessy, 1940) In monkeys, however, serum given at the *time of onset of symptoms* has not proved effective (Wyckoff and Tesar, 1939).

Significance of antibody.

The observations are somewhat conflicting. Thus, certain observers have found that the degree of resistance to infection in vaccinated mice correlates fairly well with serum antibody titer (Morgan, 1941, Morgan and Olitsky, 1941, Casals, 1943 *b*).

In rabbits, however, the presence of antibody in the CSF seemed *to be the* determining factor. Thus, if no antibody was found in the CSF, even if it was in the blood, animals succumbed to challenge (Morgan, Schlesinger and Olitsky, 1942, *Schlesinger, Morgan, and Olitsky, 1942*).

In vaccinated guinea-pigs, there may be a high degree of cerebral resistance, without much serum antibody being present (Olitsky and Harford, 1938 *c*)

***In vitro* interaction.**

There has been considerable discussion, and the position is still not clarified regarding what occurs when virus and antiserum are mixed *in vitro;* is there a stable union between virus and antibody? In the present state of knowledge, all we can do is to present the main observations, without drawing any definite conclusions.

1. Merrill (1936 *a, b*), working with eastern virus, found differences between the titers when *serum* was added to neat virus, and serial dilutions were then made, and the titers obtained when the virus and serum were mixed after being diluted separately. The titer was higher by the latter method Filtration tests of partly in-

can be immunized to resist a cerebral challenge. The degree of resistance is as high as occurs after the use of live virus (Cox and Olitsky, 1936 *a*, *c*, Beard *et al.*, 1938 *a*, Olitsky and Morgan, 1939 *b*, Morgan and Olitsky, 1941)

It is said to be easier to immunize older than younger mice sufficiently to withstand a cerebral challenge (Morgan, 1939, 1940, 1941).

Resistance induced by formolized virus wanes in the course of months, but a "booster" dose quickly raises the degree of immunity (Morgan and Olitsky, 1941)

Some work has been carried out with a formolized horse brain vaccine in the prevention of the disease in horses (Shahan and Giltner, 1935 *b*)

After prolonged mouse passage, strains may lose some of their antigenic properties (Olitsky, Morgan, and Schlesinger, 1945).

Chick embryo vaccines.

The vaccine most widely used for the immunization of horses is prepared from infected chick embryos, and formolized It can be used in the monovalent or bivalent form (Beard *et al*, 1938 *b*, Randall, 1940, Randall, Mills, and Engel, 1947). Experimentally, this vaccine induces satisfactory resistance in guinea-pigs (Lyon and Wyckoff, 1938, Mitchell, Walker, and Plummer, 1938, Schoening, 1939).

In horses, the vaccine is given in 2 doses at weekly intervals, intradermally (1 c.c.) or subcutaneously (10 c c), this dosage immunizes sufficiently to withstand a cerebral challenge for about a year (Eichhorn and Wyckoff, 1938, Lyon, 1938, Schoening, 1939, Roberts and Moore, 1939, Schoening *et al*, 1940, 1943; Simms, 1946). The vaccine has been widely used since 1938, and appears to have been re- [illegible] mple, experiences [illegible] (1945) reported [illegible] compared to 2 9 per 1,000 in unvaccinated animals.

Embryo vaccines can sensitize guinea-pigs, owing principally to antigens in egg white, ovalbumin, egg yolk, and of chicken origin (Coulson and Stevens, 1946, Stull, 1946, Engel and Randall, 1947 *a*). It is probable that formalin reduces somewhat the danger of anaphylactic reactions (Randall, Mills, and Engel, 1947). Nevertheless, anaphylactic reactions have occurred in horses (Wolfe and Trum, 1940).

Other vaccines.

Formolized tissue cultures can be used (Sanders and Molloy, 1940) Brain or chick embryo vaccines retain immunizing potency after exposure to UVL (Morgan and Lavin, 1941)

Mechanism of Resistance in Vaccinated Animals

There is little doubt that antibody present in the CSF or blood plays some part in the resistance shown by immunized animals, and this point has been discussed above The rôle of serum antibody is presumably restricted to infections in which virus reaches the CNS via the blood

There may be some part played by an acquired resistance of the nerve cells Thus, injecting western virus in vaccinated guinea-pigs, Schlesinger, Olitsky, and Morgan (1944) found a rise of temperature and recovery without signs of nervous involvement Histological changes were present, but virus did not multiply. Hurst (see above) found that immunity developed only if there had been signs of nervous involvement

Active Immunization in Man

The inoculation of chick embryo vaccine stimulates the development of virus neutralizing antibodies, but probably not in every case (Bowman, 1945, Heath, 1945) Beard, Beard, and Finkelstein (1939, 1940) used a bivalent vaccine. The response of neutralizing antibodies was higher and developed more rapidly with the

Specific antigens have been prepared from chick embryo tissue or mouse brain by extraction in the lyophilized state with benzene, toluene, or dichlorethylene (DeBoer and Cox, 1947). Espana and Hammon (1947) have modified this technique, and prepared antigens for the N. American equine viruses, and for Hammon's California virus.

Hyperimmune serum is often prepared in guinea-pigs. It is recommended that the virus be given subcutaneously, then peritoneally, and finally cerebrally (Hammon and Espana, 1947); with Hammon's California virus an injection is given cerebrally. Sera should normally be inactivated at 60° C. for 20 minutes, but if the serum is anticomplementary or if nonspecific fixation occurs, it should be heated at 65° C for 20 minutes (Casals, 1945 *b*).

Using irradiated chick embryo antigens, Brown (1947 *a*) found nonspecific fixation with some human sera. By inactivating the sera at 60° C. for 15 minutes instead of 56° C. for 30 minutes, this trouble was obviated.

Miscellaneous

Antisera do not agglutinate collodion particles mixed with virus (Donaldson and Clark, 1945).

SERUM ANTIBODIES IN MAN

Virus neutralizing and complement fixing antibodies develop in convalescence, and a distinct rise in titer should be evident about 10–14 days after onset (see, e g, Casals and Palacios, 1941 *b*). CF antibodies have been found as long as 2 to 2½ years after the illness (Casals and Palacios, 1941 *b*, Howitt, 1943).

There is little doubt that in endemic areas, subclinical immunization occurs A number of workers has found virus neutralizing antibodies in the sera of persons without any definite history of encephalitis (Olitsky and Morgan, 1939 *a*, Mitchell and Pullin, 1943, Bowman, 1945). Hammon and Reeves (1947) give the following figures for the incidence of antibodies in the general population to the western virus in Yakima 1940, 5 out of 75 (6 6 per cent) positive, 1941, 0/52 positive, 1944, 7/24 (29 3 per cent) positive It is of interest that in 1940 there were 58 clinical cases of encephalitis, in 1941 26 cases, and no cases occurred in 1944 Antibodies have not been found in the sera of persons in nonendemic areas, e g, in Quebec and Ontario (Mitchell and Pullin, 1943)

Antibodies may occur in the CSF (Howitt, 1941 *b*, Gwatkin and Moynihan, 1943)

ACTIVE IMMUNIZATION IN ANIMALS

With Live Virus

Animals that survive experimental infection are resistant to challenge, even by the cerebral route This phenomenon can be shown especially with horses, monkeys, and guinea-pigs

Immunity may also be induced by the injection of sublethal doses of virus Thus, in horses, the injection of virus subcutaneously may immunize (Records and Vawter, 1934 *a*) Working with guinea-pigs, Olitsky and Cox (1936) induced immunity by sublethal doses Howitt (1940) made similar observations in birds, and Casals (1943 *b*) in mice

Resistance waning after a few months is quickly reinforced by a booster dose (Morgan and Olitsky, 1941)

With Inactivated Virus

Formolized tissue vaccines.

Formolized animal brain tissue, presumably containing only inactivated virus, or too little live virus to be effective, is a potent antigen, and laboratory animals

western than the eastern virus, high titers being found after 7 and 14 days, respectively. After 6–9 months, most of the eastern antibodies disappear, but western antibodies remain at a high level (Beard, Finkelstein, and Beard, 1941). These workers found that the response to revaccination with a single dose was markedly higher than that following primary vaccination.

Serum antibodies were titrated by Lennette and Koprowski (1946) by the sensitive subcutaneous route in 3-day mice. Although titration by the cerebral route demonstrated little antibody response, by the other method neutralizing antibodies were found by the 3rd week after the 1st dose The peak response was 1–5 weeks after the second injection, and then fell rapidly to reach a low level 9–10 months later.

Despite theoretical possibilities (see Ch. XIII), there does not seem to be much risk of specific sensitivity developing in man (Gold and Hampil, 1940–1).

RELATIONSHIP TO OTHER VIRUSES

The western and eastern viruses have been shown to be unrelated to the following neurotropic viruses. St. Louis, Japanese B, West Nile, Russian spring-summer, or louping ill (Howitt, 1937 *b*, Shahan *et al.*, 1942; Casals, 1944), lymphocytic choriomeningitis (Howitt, 1937 *a*, *b*), vesicular stomatitis (Olitsky, Cox and Syverton, 1934), infectious encephalomyelitis of young chickens (Olitsky, 1939), and Moscow 2 virus, which is a rabies strain (Howitt, 1937 *a*, 1941 *a*).

The N. American strains are unrelated to the following viruses. infectious feline agranulocytosis (Lawrence *et al.*, 1943), Bunyamwera (Smithburn, Haddow, and Mahaffy, 1946), Roca-García's (1944) viruses, Colorado tick fever (Koprowski and Cox, 1947).

CHAPTER XCVII

VENEZUELAN EQUINE ENCEPHALOMYELITIS

EQUINE encephalomyelitis in Venezuela is caused by a virus that is similar in properties to the eastern type of the North American virus (Kubeš and Ríos, 1939, Gilyard, 1945) The Venezuelan virus is, however, antigenically distinct from the N American strains, and from the Argentine virus (Beck and Wyckoff, 1938, Kubeš and Ríos, 1939, Kubeš and Diamante, 1942).

The virus probably also occurs in equines in Colombia (Soriano Lleras and Figueroa, 1942; Samper and Soriano Lleras, 1943)

It has been recovered from horses and mules in Trinidad, where in 1943 there were about 70 fatal equine cases (Kubes, 1944, Randall and Mills, 1944).

A natural case of infection in man has been reported from Trinidad (Gilyard, 1944, Randall and Mills, 1944) The virus has been recovered from the blood and upper respiratory tract of a laboratory worker suffering from a mild acute febrile illness (Casals, Curnen, and Thomas, 1943), the same workers have described an-
[illegible] have been described by Lennette and
[illegible] Cox (1947 *a*), which serves to em-
[illegible] nplement fixing and virus neutralizing
[illegible] Curnen, and Thomas, 1943) Gallia
and Kubeš (1944) described the presence of virus neutralizing antibodies in the sera of a number of laboratory workers who probably contracted an inapparent infection.

It seems very likely that the infection is borne by mosquitoes, and the virus has been transmitted to guinea-pigs by *Aedes aegypti*, *A. albopictus*, and *A geniculatus* (Roubaud *et al*, 1941). Virus was recovered in Trinidad from *Mansonia titillans* naturally infected, and this species was shown to be infective by bite (Gilyard, 1944)

The virus is pathogenic experimentally for horses, guinea-pigs, rabbits, and mice (Beck and Wyckoff, 1938, Kubeš and Ríos, 1939, Kubeš, 1944, Koprowski and Lennette, 1946 *a*) Mice of all ages are highly susceptible to extraneural inoculation
(Lennette and [illegible]
as to cerebral [illegible]
not significantly [illegible]
from the N A [illegible]
formed by the peritoneal route in mice up to 200 days of age (Lennette and Koprowski, 1944 *b*)

In the egg, the virus can be inoculated in the yolk sac or on the chorio-allantoic membrane (Kubeš and Ríos, 1939, Kubeš, 1944). Virus multiplies rapidly, and disseminates throughout the egg, reaching its highest concentration in the embryo Virus can be titrated by egg inoculation, and the results are similar to those obtained in mice (Koprowski and Lennette, 1944)

The virus has been grown in tissue culture, in serum-Tyrode and minced chick embryo (minus the CNS). Studying the effect of continued culture passage on invasiveness, the lethal effect of the virus on cerebral inoculation in mice was found not to be affected by 74 passages but an effect was noted on peripheral inoculation The first indication that virulence by the extraneural route was being lost on passage was obtained in older mice (28 days and upward) After repeated culture [illegible]

CHAPTER XCVIII

RUSSIAN SPRING-SUMMER (FAR EASTERN) ENCEPHALITIS

In the past ten years or so, Russian workers have thoroughly investigated a type of tick-borne encephalitis occurring mainly in the virgin woodlands (*taiga*) of the far eastern part of the Soviet. It is probable that the disease existed as far back as 1914, and perhaps earlier, although it only became a problem in about 1935.

More recently, a western form of the disease has been recognized in European Russia.

Most of th[illegible] of useful articles and [illegible] 940, 1941, Propper-Gra[illegible] 940; Solo-viev, 1944; S[illegible] Particular mention mus[illegible] printed in the *Bulletin of Hygiene*, to which suitable acknowledgment is made.

In the compilation of this article, we have freely consulted the valuable reviews of Smorodintsev (1940) and Silber and Soloviev (1946). (As we have not been in a position to consult or read any Russian language papers, we have to depart from our usual practice as regards references, and can only mention English language articles in which the appropriate original Russian references are quoted. Silber and Soloviev (1946) give a full Russian bibliography.)

CLINICAL FEATURES

The incubation period of far eastern encephalitis is 8–18 days. The onset is sudden, with rise of temperature, head[illegible] pains in the neck T[illegible] sis may involve the [illegible] sleepy, and may have epileptifo[illegible] convulsions. Various types of temperature reaction have been described. In severe cases, the bulb is involved with consequent paralysis of vital functions.

There is a slight increase in lymphocytes in the CSF, and an increase in protein.

Sequelae include paralysis and atrophy of the muscles of the neck and brachial girdle. Parkinsonism is said not to occur.

The mortality of the eastern form is about 30 per cent, death occurring 3–8 days after onset.

In some cases, the picture is more of a serous meningitis than an encephalitis.

Cases of the western type occurring in European Russia tend to be milder, and abortive forms are more common.

DISTRIBUTION OF VIRUS

Apart from the tissues of the central nervous system, virus can be found in the spinal fluid, blood, liver, spleen, urine, nose, and throat (see Smorodintsev, 1940, Silber and Soloviev, 1946). It has also been recovered from the pharynx of contacts.

PATHOLOGICAL FEATURES

The features are those of an acute nonsuppurative meningo-polio-encephalomyelitis (Smorodintsev, 1940, Silber and Soloviev, 1946). The meninges are inflamed, being infiltrated with round and polymorph cells. The brain is congested, and there are numerous hemorrhages in the brain stem, medulla, and spinal cord.

the order of sensitivity (Koprowski and Lennette, 1946 *b*). first, intraperitoneal inoculation in mice; and then of equal sensitivity come intracerebral inoculation in mice and inoculation in chick embryos Complement fixation can also be demonstrated (Casals, 1945, 1947).

Guinea-pigs can be actively immunized with formolized virus (Beck and Wyckoff, 1938), and horses have been vaccinated with chick embryo vaccine (Kubeš and Ríos, 1938). Hyperimmune sera can be prepared in rabbits by injection of formolized followed by live virus (Koprowski and Lennette, 1946 *b*).

The virus is not related antigenically to the virus of Colorado tick fever (Koprowski and Cox, 1947 *b*).

tine (Pavlovsky and Soloviev, 1940). Transmission of infection to man or animal is by salivary contamination of the bite.

In laboratory experiments, *Ixodes persulcatus* can be infected by feeding on mice (Pavlovsky and Soloviev, 1940). *Ixodes persulcatus* is thought to be the only tick transmitting the far eastern form of the disease.

Ixodes ricinus. A virus thought to be that of spring-summer encephalitis has been isolated from larvae and nymphs of *Ixodes ricinus* in White Russia and Karelia, and this tick has been held to be the vector of the western form of the disease (Chumakov and Naidenova, 1944; Chumakov *et al*, 1944). Silber and Shubladze (1945 *b*), however, raise the question of possible confusion with the virus of louping ill Silber and Soloviev (1946) conclude that the epidemiology of the western form of the disease is insufficiently studied, and any conclusions as to its method of spread are premature

Other ticks. In laboratory experiments, of unknown practical application, virus has been found to survive in the following ticks *Dermacentor silvarum, D pictus, D nuttalli, Rhipicephalus turanicus, Rh. bursa, Haemaphysalis concinna, Hyalomma asiaticum, H. dromedarium, H. turkmeniense;* transovarial infection has been noted in *D. nuttalli, Rh. turanicus, H asiaticum, H turkmeniense,* and *H. dromedarium* (Smorodintsev, 1940, Chumakov, Petrova, and Sondak, 1945). *Ornithodoros moubata* has also been infected (Parker, 1942).

Persistence of virus in ticks. The question arises of whether virus can survive in the tick population over the severe Russian winter. There is little doubt that it can do so, and that ticks constitute an important, probably the main, reservoir of infection with the far eastern virus Thus, it has been shown that once acquired, virus is transmitted to successive stages in metamorphosis, and transovarially. Although it has been found that eggs and unfed larvae perish at –7° C, all other stages can survive down to –30° C, which temperature is not reached under the snow covering (Pshenichnov and Khramushen, 1943) Demonstrating the persistence of virus in laboratory experiments with *I ricinus*, Chumakov (1944), found that it could be recovered from nymphs of the 2nd generation 11 months after collection from a 2nd generation imago after 15–18 months, and from larvae and nymphs of the 3rd generation after 22–26 months Transovarial transfer of virus was noted through 3 generations

Prevention of tick bites Ticks are found in the lower zones of vegetation, not higher than 1 meter from the ground. They can be kept away from man by protective clothing tied tightly at the ankles, wrists, and neck, and by chemically impregnated garments (Eskin, Chagin, and Murovannyi, 1944)

Animal hosts of ticks Ticks feed on many animals, and man is only an accidental host No less than 63 species of mammal may act as host, but the hosts of the adult of *Ixodes* are only 25, mostly wild carnivores, ungulates, dogs, pigs, cattle, sheep, horses, and goats (Kuzyakin, 1942)

Numerous animals have been found infected, either by isolation of virus, or by demonstration of serum antibodies (Chumakov, Vorobieva, and Sofronova, 1940, Smorodintsev, 1940, Pavlovsky, 1941, Soloviev, 1941, 1944, Kalabukhov and Shubladze, 1946) The following have been incriminated hare, squirrel, chipmunk, red-backed mouse, hedgehog, vole, mole, water rat, wild and wood mouse, hazel grouse, and other birds

The virus has been isolated from the brains of cows killed near Brest-Litovsk, and antibodies have been found in the sera of bovines in this district (Chumakov and Naidenova, 1944)

Animals obviously play an important rôle in the epidemiology of Russian encephalitis, as they serve to feed the tick vectors Animals almost certainly disseminate infected ticks over a wide area, but it is doubtful whether they constitute an important reservoir of infection The period of viremia is short, and, therefore, animals can be infective for ticks for only a brief period

The severest lesions occur in the gray matter of the cord and medulla, changes are less severe in the gray matter of the base of the brain, and are slight in the cortex. The types of lesion seen in the various areas include acute perivascular infiltration, vasculitis and hyaline thrombosis, a diffuse and focal infiltration of the gray matter; degenerative changes in the ganglionic cells of the gray matter of the medulla and cord, progressing as far as complete destruction and neuronophagia, the infiltrating cells are mostly lymphocytes, with a few polymorphs and glial cells The changes are likened to those of St. Louis and Japanese encephalitis.

EPIDEMIOLOGY

Geographical Distribution

The disease occurs mainly in Siberia and the Far East of Russia, but also in th Urals, the pre-Urals, Volga, Karelia, White Russia, Kuibishev, Leningrad and Kalinsky (see Soloviev, 1944, Kalabukhov and Shubladze, 1946). A distinction is made between far eastern encephalitis and the milder western variety found in central and western Russia. In European Russia, it is probable that many cases diagnosed as atypical poliomyelitis, serous meningitis, and "post-grippe" encephalitis have really been due to invasion by the encephalitis virus (Chumakov and Seitlenok, 1940).

Seasonal Incidence

The majority of far eastern cases occurs in the last 10 days of May and the first 10 of June, the whole season extends from the end of April to August. The western cases occur mainly in the summer.

Type of Locality and Worker Involved

The far eastern disease occurs chiefly in the *taiga* or uncleared virgin forest The main incidence is in recently built villages in these forests. The chief victims are the young male lumber workers The incidence in recently cleared relatively uninhabited *taiga* is twice as high as in the more colonized parts

Rôle of Ticks [1]

The occurrence of cases in those who work in the *taiga* suggests that the vector of the far eastern disease may be an arthropod, and up to 75 per cent of cases actually have a history of tick bite within the incubation period. The curve of the incidence of ticks is almost exactly the same as that of the disease, but 10–14 days earlier

Ixodes persulcatus This tick is the vector of the disease *in the far eastern Soviet*. Virus has been recovered from ticks by inoculating mice, or by allowing them to feed on mice. The tick can absorb virus at any stage of its metamorphosis by feeding on an infected animal, once acquired, virus is transmitted to the subsequent developmental phases, and to the offspring transovarially. Virus has been recovered from larvae, nymphs, male and female adults, and hibernating adults (before feeding) collected in endemic foci (Levkovich and Skrynnyk, 1940, Smorodintsev, 1940, Pavlovsky, 1941, Ryzhov and Skrynnyk, 1941, Chumakov *et al*, 1944) Virus is present in all organs of infected ticks, especially the brain, sex organs, and intes-

[1] For the benefit of those who are not familiar with the subject, the biology of ticks is briefly as follows (see Whittick, 1943) Mating between adults occurs on the host [illegible] s, [illegible] in [illegible] ng
8-legged nymph. [illegible]
rise to the adult Mating occurs on the host and the cycle renews

IMMUNITY MECHANISMS

Experimental

Active immunity.

Mice that recover from infection become resistant, inoculation of a sublethal dose also immunizes (Soloviev, 1944).

Mice can be actively immunized by intraperitoneal injection of formol-inactivated virus (e.g., 10 per cent brain, 0.5 per cent. formol), mice so treated will resist a challenge dose of live virus injected by a peripheral route (Levkovich and Smorodintsev, 1940, Smorodintsev, 1940, *et al.*, 1941; Casals and Olitsky, 1945).

Serum antibodies.

Complement fixation can be demonstrated between antisera and brain antigens, the presence of a positive fixation test in the sera of immunized mice indicates a high degree of resistance to challenge (Casals, 1944; Casals and Olitsky, 1945): Casals (1947) gives details of his technique of preparing antigen by alternate freezing and thawing, inactivation is by exposure to UVL or heat. Antisera are readily prepared in guinea-pigs recovered from a cerebral inoculation (Hammon and España, 1947).

Virus neutralizing antibodies develop in mice on recovery from infection or after injection of formolized virus. These antibodies can be tested by injecting virus-serum mixtures peritoneally in mice, less antibody is demonstrated if mixtures are inoculated cerebrally (Smorodintsev *et al.*, 1941; Casals and Olitsky, 1945) Olitsky and Casals (1947) describe in detail the technique of virus neutralization tests using the cerebral route (see Ch. XI).

Virus neutralizing antibodies have been demonstrated in the serum of infected monkeys and hyperimmune rabbits (Silber and Shubladze, 1945 *a*, Silber and Soloviev, 1946), and hyperimmune goat serum has been used in man (see below).

Nonspecific virus neutralization has been demonstrated, and the lipoid fraction of normal animal serum rapidly reduces the infectivity of suspensions of Russian spring-summer virus (Casals and Olitsky, 1947)

As regards the *mechanism of resistance* in immune mice, it is probable that antibody plays an important rôle Casals and Olitsky (1945) found that the degree of resistance correlated with the presence and titer of neutralizing antibodies, if these were estimated by the peritoneal route in mice Further, there was a drop in titer of antibody following the inoculation of virus.

Passive immunity.

Antiserum exerts a definite protective effect in infected mice Thus mice given serum 1–15 days before infection may survive, serum may be administered up to one day after infection (Chumakov, 1940).

In Man

Dwellers in endemic areas acquire an immunity, presumably by subclinical attack The incidence of the disease in newcomers to the *taiga* is about 2½ times that in older residents (Soloviev, 1944, Silber and Soloviev, 1946).

Man can be immunized by the subcutaneous injection of formol-inactivated virus, and good results have been obtained in endemic foci, the incidence of the disease being reduced by over ten times (Smorodintsev, 1940, Smorodintsev, Levkovich, and Dankovsky, 1940, Smorodintsev *et al*, 1941)

Virus neutralizing antibodies develop in man on recovery from infection, and can be demonstrated after 2–4 weeks, reaching a maximum after 2–3 months (Chumakov, 1940, Smorodintsev, 1940, Silber and Soloviev, 1946).

PROPERTIES OF THE VIRUS

Antigenic Structure

So far, no evidence has been brought forward regarding antigenic heterogeneity, and it appears that all strains are similar in respect to antigenic structure (Smorodintsev, 1940; Silber and Soloviev, 1946).

Infection in Experimental Animals

Mice.

Virus can be isolated from human material most readily by cerebral injection in mice. Mice can also be infected nasall [illegible] and *subcutaneously (Smorodintsev, 1940, Casals* [illegible] 1946). Symptoms develop after about 4–10 [illegible] tive and later sluggish, with paralysis of the hind quarters Virus is found in the blood shortly after inoculation, and again in the terminal phase. It can be found in the urine from 3–6 days after infection. The histological appearances resemble those found in man.

Strains of mice bred selectively for susceptibility and resistance to louping ill and St. Louis viruses proved similarly susceptible and resistant to Russian virus (Casals and Schneider, 1943).

Monkeys.

On cerebral injection, encephalitis develops in 5–9 days, from which the animals may recover (Smorodintsev, 1940, Silber and Shubladze, 1945 *a*, Silber and Soloviev, 1946) They show fever and paralysis

Sheep.

Lambs have been infected by the cerebral route (Smorodintsev, 1940, Silber and Soloviev, 1946) They develop paralysis and fever, and die in about 7–10 days *Histologically, in addition to inflammatory changes, the brain shows some necrosis* of purkinje cells.

Other animals.

A number of other animals may harbor virus after injection the wild mouse, gray rat, goat, wolf, hedgehog, oriental water rat, hamster, and various birds—siskin, redpoll, goldfinch, and red breast (Smorodintsev, 1940, Soloviev, 1944, Silber and Soloviev, 1946). Guinea-pigs develop only slight fever on cerebral injection (Hammon and Espana, 1947)

Some Other Properties

The virus is grown in minced chick embryo in Tyrode's solution (Smorodintsev, 1940)

The virus passes through Seitz pads, Berkefeld V, N, and W candles, and Chamberland L_2, L_3, and L_5 filters (Smorodintsev, 1940, Silber and Soloviev, 1946) It is preserved in glycerol (Smorodintsev, 1940), and maintains infectivity when frozen and dried It is destroyed at 60° C in 10 minutes, and by 1 per cent phenol (Silber and Soloviev, 1946) Formol (1 500–1,750) destroys the virus in a 1 per cent. brain emulsion at ice box temperature in 20 days, at room temperature in 6 days, and at 37° C in 3 days (Levkovich and Smorodintsev, 1940, Smorodintsev *et al*, 1941).

Antibodies can be demonstrated in the sera of residents in endemic areas (Silber and Soloviev, 1946).

Serum from hyperimmune animals (goats) or convalescent human beings is a useful therapeutic agent in man, if given intrathecally and intramuscularly early and often (Smorodintsev, 1940). It may also be used prophylactically in the case of persons staying only a short time in an endemic area (Chumakov, 1940).

RELATIONSHIP TO OTHER VIRUSES

Louping ill Russian virus is closely related antigenically to that of louping ill, as shown by complement fixation, neutralization, and intraperitoneal cross resistance tests in mice (Casals and Webster, 1943, 1944; Casals, 1944). Sheep are sensitive to both viruses, but whereas the Russian virus produces fatal paralysis, louping ill causes ataxia and tremor (Silber and Soloviev, 1946).

Japanese, St. Louis, and West Nile viruses. Here the results are somewhat conflicting. Thus, Casals (1944) found that the subgroup represented by these 3 viruses was unrelated to Russian or louping ill viruses. Russian observers, however, claim that Russian and louping ill viruses are related to Japanese and St. Louis viruses. Thus Levkovich (1940) showed that animals vaccinated with Russian virus were resistant to challenge with Japanese and St. Louis viruses. It has been claimed that Japanese sera exert a weak neutralizing effect on Russian virus. Russian sera were found to have a strong neutralizing effect on Japanese virus, but only a weak action on St. Louis virus Russian virus could completely absorb antibodies from Japanese serum, but Japanese virus could only partly absorb antibodies (Smorodintsev, 1940, Silber and Soloviev, 1946).

Other viruses Russian virus is not related to equine encephalomyelitis virus (Casals, 1944), and it is not neutralized by the sera of convalescents from encephalitis lethargica (Smorodintsev, 1940). It is not related to the virus of another tick-borne disease, Colorado tick fever (Koprowski and Cox, 1947)

perivascular cuffing, there is a great diminution in the numbers of Purkinje cells, and neuronophagia and reactionary gliosis may be present in varying degree.

There may be perivascular cuffing, nerve cell destruction, and neuronophagia in the medulla and spinal cord also, but these are very variable features. The essential lesion in the naturally occurring disease is, therefore, the great destruction of nerve cells, more particularly the Purkinje cells of the cerebellum Here it may be mentioned, in anticipation, that similar appearances are found in the experimentally infected monkey. The mouse and pig, however, show much less evidence of cerebellar nerve cell damage

Epizootology

Distribution of the disease Louping ill occurs mainly in lambs and yearlings, but the highest death rate is among rams bought in for breeding purposes The disease occurs in the West Highlands and border districts of England and Scotland The affected farms have usually rough hill grazing and are infested with ticks The main louping ill season is from mid-March to mid-May with, in the West Highlands, an autumn outbreak as well

Method of transmission The work of the Moredun investigators (e g, Gordon *et al*, 1932 *a*; MacLeod and Gordon, 1932) has conclusively proved what had long been suspected, namely, the rôle of the tick *Ixodes ricinus* in the spread of louping ill The following are the main points elicited (1) the virus of louping ill can be recovered from ticks that have fed on sheep during the prodromal febrile period, (2) the virus can be demonstrated in the tissues of nymphs which, as larvae, have fed on infected sheep, (3) the infection can be transmitted to sheep by the bites of female and nymphal ticks which have acquired the infection respectively as nymphs and larvae, (4) ticks are capable of producing louping ill within 12 days of molting, or as soon as they are able to attack A publication (*Bulletin*, 1938) describes the life history and economic significance of ticks

The influence of tick-borne fever

It has already been mentioned that many sheep infected with louping ill show no more than the prodromal febrile reaction and do not develop symptoms referable to the central nervous system For the development of these symptoms the coexistence in the tick-infested sheep of a second disease, tick-borne fever, is a most important factor Cross immunity experiments have shown that the causal agent of this tick-borne fever is perfectly distinct from the virus of louping ill (see Gordon *et al*, 1932 *a*, *b*, MacLeod and Gordon, 1932, 1933)

Immunity reactions and prevention

Many animals on an infected farm are immune to injections of virus, presumably owing to a previous mild or abortive attack giving rise to a state of active immunity

Subcutaneous inoculations of formolized sheep cord and brain produce antibodies capable of neutralizing virus introduced into the general circulation, although intracerebral injections are still capable of inciting infection Such vaccines can be used in prophylaxis of the disease, the vaccine has been successfully used on a large scale by Gordon and his associates (see Edward, 1947 *b*) Edward (1947 *b*) reports good results in protecting sheep by the use of formolized vaccine containing sheep brain, cord, and spleen The challenge virus was given subcutaneously, and 3 days later starch was given cerebrally It was argued that in immune animals virus would not proliferate in the blood, and so the cerebral starch would not localize virus in the brain

Animals that have withstood intranasal, intradermal, or subcutaneous injections of living virus resist intracerebral injection Unfortunately this method of vaccination appears to be rather dangerous

In an article (*Bulletin*, 1938), which should be consulted by those interested in louping ill, practical methods of dealing with ticks by dipping and other measures are discussed

LOUPING ILL IN MAN

Although louping ill has been recognized in sheep for over a century, there has never been any suggestion of transmission to human beings taking place under natural conditions Thus there have been no reports of unusual nervous symptoms in shepherds, farmers, veterinary surgeons, or others coming in contact with in-

CHAPTER XCIX

LOUPING ILL[1]

This disease of sheep, occurring in Scotland and the north of England, has been known for over a century, and during the past 50 years numerous attempts have been made to define its causal agent (see Pool, Brownlee, and Wilson, 1930, Pool, 1931 *a*, *b*; Pool, 1933–4) A variety of bacteria, toxemias, and other causes has been blamed, but no real progress resulted until Pool, Brownlee, and Wilson (1930) succeeded in infecting both pigs and sheep experimentally, by intracerebral injections of sheep brain and cord.

Mackie (see Alston and Gibson, 1931) was the first to demonstrate that the etiological agent was a filtrable virus, by preparing infective Berkefeld filtrates of sheep brain. Under his direction Alston and Gibson (1931) succeeded in transmitting louping ill to mice by intracerebral injection. The discovery of the susceptibility of mice enormously facilitated the subsequent investigations into the natural disease. Greig *et al.* (1931) demonstrated that Berkefeld and Chamberland filtrates were capable of infecting sheep.

The bulk of the work on louping ill in sheep has been carried out in Scotland at the Moredun Institute, Midlothian

Louping Ill in Sheep

The following account is largely summarized from the publications of the Moredun investigators (Pool, Brownlee, and Wilson, 1930, Greig *et al*, 1931; Pool, 1931 *a*, *b*; Brownlee and Wilson, 1932, Gordon *et al*, 1932 *a*, *b*, MacLeod and Gordon, 1932, Gordon, 1933–4, 1934; Pool, 1933–4)

Features of the disease

One of the most characteristic features is a diphasic febrile reaction During the prodromal period the animal is indisposed, the temperature raised, and the virus can be demonstrated, by animal injection, in the blood Many mild and abortive cases may not show any further evidence of infection with louping ill than this preliminary pyrexia Such cases can only be diagnosed with certainty by injection of mice with citrated blood In severer cases, however, symptoms of invasion of the central nervous system subsequently appear, along with a second attack of pyrexia During this attack, moreover, no virus is demonstrable in the blood It has been shown (*vide infra*) that another disease of sheep, tick-borne fever, is an important factor predisposing to involvement of the central nervous system

The commonest nervous symptoms are champing of the jaws, tremors and "tremblings," paresis of one or more limbs, cerebellar ataxia, and leaping movements into the air. The case mortality rate is high

Pathology.

The pathological features of the naturally occurring disease have been well described by Brownlee and Wilson (1932) and are those of an acute encephalomyelitis

Histologically, the cerebral meninges show a diffuse congestion and infiltration with round cells and occasional polymorphs The cerebral cortex shows the following changes in varying degree perivascular cuffing, degenerative changes in the nerve cells, and diffuse infiltration with polymorphs

The main changes are, however, to be found in the cerebellum The meninges are congested and infiltrated with round cells The substance of the cerebellum shows diffuse

[1] Although this disease is primarily one of animals, and only rarely occurs in man, we have discussed it fully in view of the possibility that the viruses of louping ill and Australian X disease are identical, or else closely related (see also Ch C)

inasmuch as no virus was isolated from the brain by monkey or mouse inoculation, and as no serum was available, we do not consider the evidence sufficient to justify any conclusions as to whether this case was one of louping ill or not. If it were a case, then some feasible explanation of how the child came to be infected with the virus should be forthcoming.

CHARACTERISTICS OF THE LOUPING ILL VIRUS

Animal Experiments

Sheep.

The infection has been transmitted to sheep (e g, Pool, Brownlee, and Wilson, 1930, Greig *et al*, 1931; Brownlee and Wilson, 1932, Lépine, 1931 *a*, Edward, 1947 *b*).

Following intracrebral injection a thermal reaction occurs (above 106° F), reaching its acme about the 4th to 5th day and then subsiding In certain cases the sheep then becomes dull and shows incoordination, tremors, salivation, and champing of the jaws A day or two later it becomes paralyzed and falls to the ground, eventually dying in coma

Histologically, the cerebrum shows a well marked meningeal reaction, and in the cortex perivascular cuffing and some diffuse cellular infiltration The cerebellum shows a varying destruction of the Purkinje cells, with neuronophagia and accompanying microglial proliferation Perivascular cuffing may be present in addition, in the hippocampus, medulla, and cord The Golgi apparatus of the nerve cell undergoes changes consequent on invasion by the virus There is hypertrophy, a reduction in the number of filamentous elements, and a reduction in the amount of Golgi substance in the cell processes, fragmentation ensues (Gresson and Zlotnik, 1947).

The sheep can also be infected by the intraspinal, intra-ocular, ocular, intrasciatic, intravenous, and subcutaneous routes Edward (1947 *b*) could only produce encephalitis in about half the sheep inoculated subcutaneously In some animals inoculated in June and July no encephalitis occurred, pointing to the importance of seasonal and other factors determining invasion of the brain after local growth of virus Encephalitis occurred with greater regularity if starch was injected cerebrally

The virus is widely distributed in the brain, cord, sciatic nerve, blood (from 3 to 7 days after inoculation), spleen, voluntary muscle, and popliteal and mesenteric lymph glands of infected sheep

Pigs.

The virus can also be transmitted to the pig, but serial passage is not possible (Pool, Brownlee, and Wilson, 1930, Greig *et al*, 1931, Brownlee and Wilson, 1932) Typical louping ill develops after 5 to 6 days

Histologically, the reaction is of a different order from that found in the sheep and monkey, being predominantly interstitial The meningeal reaction is pronounced, and there is much perivascular cuffing The Purkinje cell layer is widely infiltrated, but there is relatively little cell destruction

Mice

Following the discovery made by Alston and Gibson (1931) the high susceptibility of mice has been abundantly confirmed (Greig *et al*, 1931, Lépine, 1931 *c*, Czardowska-Gladney and Hurst, 1931, Hurst, 1931, Brownlee and Wilson, 1932, Webster and Fite, 1932–3, Fite and Webster, 1933–4, Haber, 1939 *a*, *b*, *c*, Edward, 1947 *b*) Strains specially susceptible or resistant can be bred (Webster and Fite, 1932–3, Casals and Schneider, 1943).

An incubation period of 5 to 9 days follows intracerebral injection. During the last 12 to 24 hours prodromata may appear, such as irritability and hyperesthesia, or sometimes immobility. The symptoms of the established disease are as follows

fected sheep. There does not appear to be any method whereby the virus can become transmitted from a sheep suffering from louping ill to man.

Of great interest, however, are certain records of cases of louping ill infection occurring in laboratory workers. Rivers and Schwentker (1932–3, 1934) were the first to draw attention to this hitherto unreported human disease. They described 4 cases, each person having worked, at the time of being taken ill, with louping ill [illegible] at Britain. Subsequently Wiebel [illegible] worker, this time in Germany [illegible]

Presumably, infection was massive, with infective animal tissue, the virus probably entering via the respiratory passages.

Clinical Features

Prodromal period. Two of Rivers's and Schwentker's cases had a preliminary illness lasting approximately a week. The patients were febrile, suffered from headache, malaise, and backache, and were evidently prostrated. The cases then improved and kept well for about another week when the symptoms of the disease proper appeared.

Course of the disease. The following symptoms arose either *de novo* or after prodromata Nervous manifestations included headache, diplopia, drowsiness and mental confusion, photophobia, stiffness of the neck, vomiting, blurring of the optic disks, and weakening of the deep reflexes. Cerebellar ataxia was noted only in Wiebel's case A retrobulbar neuritis developed in one of Rivers's cases The cerebrospinal fluid was frequently blood-tinged, apparently unassociated with trauma, the pressure was raised, the cell count varied up to 60 cells per c mm, mainly mononuclears, and there was often an increase of globulin General pyrexial disturbances were always present and the blood showed a polynucleosis up to 17,000 per c mm Two of Rivers's cases were originally diagnosed as epidemic encephalitis, one as influenza, and the 4th as tuberculous meningitis Rivers and Schwentker failed to find any virus in the blood and cerebrospinal fluid of 2 cases examined. Wiebel, however, isolated the virus from the serum of his case.

Immunity Reactions

On recovery all the 5 cases described showed virus neutralizing serum antibodies This fact clinched the originally somewhat tentative diagnosis of human infection with louping ill virus.

Rivers and Schwentker found virus neutralizing bodies in the serum of another laboratory worker and in one other person, out of almost 60 tests on various human sera. Neither the laboratory worker nor the other person (a sufferer from obesity) had had any recent manifestations of illness However, whereas the first person had been in contact with the virus, the second had never had the remotest contact therewith, as far as could be ascertained Complement fixing and virus neutralizing antibodies probably persist for at least 10 years (Casals and Webster, 1944).

Johnston and Goodpasture's (1936) Case

These workers recorded the case of a Negro child who developed a fatal nervous disease some few days after a burn The child died in coma after showing convulsions The whole illness was of very short duration Postmortem changes were restricted to the brain and were those of an acute, diffuse, nonsuppurative encephalitis. The cerebrum, basal ganglia, pons, medulla, and cerebellum showed a perivascular lymphocytic infiltration The important change, however, concerned the cerebellum where there was gross loss of Purkinje cells, with necrosis and neuronophagia. On the strength of the similarity of the child's lesions to those of experimental louping ill of monkeys, Johnston and Goodpasture suggested they were dealing with a virus producing lesions resembling those of louping ill However,

ing degrees of perivascular cuffing, nerve cell destruction, and gliosis. Generally, if the lesions are advanced in the cortex they are mild in the stem and cord, and vice versa.

The infection can also be transmitted intranasally (under light etherization) as Galloway and Perdrau (1935) showed using *Macaca mulatta*. After an incubation period of approximately a fortnight symptoms appear, exactly as already described. The path followed to the central nervous system is a steadily progressive one. After 5 days no virus can be demonstrated in the brain, but it appears after 8 days in the olfactory lobe. After 12 days it can be demonstrated in all parts of the brain and cervical cord, while by the 16th day it has spread even to the peripheral nerves.

No infection results after intravenous inoculation unless the brain has been previously traumatized (Galloway and Perdrau, 1935).

Following intracerebral inoculation the virus appears in the blood after 2 to 4 days, but disappears shortly before death The virus can be demonstrated in the cerebrospinal fluid after intranasal inoculation, but only rarely in the blood or elsewhere.

Other animals.

Field voles These animals resemble mice in their susceptibility and can be infected intracerebrally, and by intraperitoneal injection if the virus is localized in the brain by an injection of starch (Findlay and Elton, 1933). Histologically, the lesions resemble those described in mice by Hurst (*vide supra*). It should be remembered that voles live in pastures affected by louping ill, and may conceivably play some part in the spread of the disease.

Rats. Burnet (1936 *b*) has shown that rats acquire an inapparent (subclinical) infection after intranasal as well as after intracerebral inoculation (see also Greig *et* ... or 8th da[illegible] ... These an ... spread to

Other experiments.

Experiments have been conducted on the simultaneous infection of mice with louping ill and rabies, and louping ill and LGI viruses (Levaditi, 1942 *a*, *b*).

Morphology

The virus measures from 15 mμ to 20 mμ as estimated by filtration through collodion membranes (Elford and Galloway, 1933), and 27 mμ to 22 mμ as estimated by the inverted capillary tube technique (Tang, Elford, and Galloway, 1937). The eosinophilic inclusions of Hurst (1931) have already been described as occurring in mouse brain Findlay (1932) found similar bodies in monkey tissue, which, as they [illegible]

and

charged at pH 7 3 (Lepine, 1931 *b*)

Cultivation

Rivers and Ward (1932–3), using chick embryo, monkey serum, and Tyrode's solution, obtained definite evidence of virus multiplication in tissue cultures of the Li and Rivers type (see also Wilson, 1945).

Burnet (1936 *a*, *b*) found the virus to be propagated readily in the developing hen egg, producing numerous foci of opacity (see also Burnet, Keogh, and Lush, 1937)

The embryo is frequently killed by the virus and appears jaundiced, but some-

tremblings, tremors, spasmodic contractions of the head and thoracic muscles, clonic or tonic convulsions, and incoordination. Shortly before death, paresis of one or more limbs occurs and the animal is usually dead by the 8th to 10th day after injection.

Histologically, brains of mice dying from encephalitis show marked perivascular and diffuse lymphocytic infiltrations in the basal nuclei and cerebral cortex. In the brain stem and spinal cord acute nerve cell destruction is the most noticeable feature. There is widespread neuronophagia in the cord and the appearances closely resemble those of poliomyelitis. The cerebellum may be severely damaged with nerve cell destruction or may escape in a remarkable way.

Inclusion bodies have been described by Hurst (1931); they occur in the neurons of the brain stem and cord and less commonly in the Purkinje cells and cells of the basal nuclei. They are found in the cytoplasm, as single or multiple, eosinophilic, round or oval bodies of 1 to 8 μ in diameter.

Mice can also be infected intranasally (Webster and Fite, 1932–3; Webster, 1933, Fite and Webster, 1933–4). Following such instillation virus is present in the blood from the 2nd to the 6th days, when the animals become ill (with features already described) and the virus tends to disappear. As a rule, virus is not generally present in the brain until the 3rd day, nor are histological lesions noted until the 5th day. Rake (1937) has shown that the virus has reached the forebrain 24 hours after nasal instillation.

Alston and Gibson (1931) noted contact infection in some of their cages, but this method of spread does not appear to have been recorded by other workers. The virus can be transmitted by intrasciatic and intra-ocular injections, encephalitis developing (Lépine, 1931 c).

After 40 mouse passages the virus still retained its infectivity for sheep (Elford and Galloway, 1933) The virus is widely distributed in the internal organs of mice dead of louping ill infection.

Burnet and Lush (1938) have carried out an important study on the pathogenesis of infection following injection by routes other than the intracerebral As indicators of the presence of virus in various tissues they used the chorio-allantois in lieu of animals

After intraperitoneal injection they found that the virus usually enters the central nervous system by the olfactory mucosa, and spreads by the olfactory bulbs They showed that trauma to the cerebrum permits virus to enter at the site of damage

Following intranasal injection the virus soon enters the olfactory bulbs, titrations showed that the virus proliferates there to a considerable extent before it can be detected in other parts of the brain Later, virus disseminates widely through the nervous system and can be found even in the sciatic nerve

Monkeys.

The infection has been transmitted to monkeys by Hurst (1931), Findlay (1932), and Galloway and Perdrau (1935).

Some 4 to 5 days after intracerebral inoculation of virus the animal becomes less active, and shows muscular weakness and tremors, while nystagmus may occur With the progress of the infection evidences of cerebellar ataxia become noticeable, the animal is clumsy, unsteady, and bumps into obstacles Eventually the animal collapses and lies on its side Despite passing through such a severe infection recovery may occur. Histologically, the cerebellar lesions are the most noticeable There is widespread destruction and sometimes total disappearance of the Purkinje cells, but little reactionary gliosis Inclusions similar to those described by Hurst (1931) in the mouse have been described in the monkey by Findlay (1932) They occur most frequently in the neurons of the pons and midbrain and less commonly in the spinal cord and Purkinje cells The cortex, brain stem, and cord show vary-

ing degrees of perivascular cuffing, nerve cell destruction, and gliosis Generally, if the lesions are advanced in the cortex they are mild in the stem and cord, and vice versa.

The infection can also be transmitted intranasally (under light etherization) as Galloway and Perdrau (1935) showed using *Macaca mulatta*. After an incubation period of approximately a fortnight symptoms appear, exactly as already described The path followed to the central nervous system is a steadily progressive one. After 5 days no virus can be demonstrated in the brain, but it appears after 8 days in the olfactory lobe. After 12 days it can be demonstrated in all parts of the brain and cervical cord, while by the 16th day it has spread even to the peripheral nerves

No infection results after intravenous inoculation unless the brain has been previously traumatized (Galloway and Perdrau, 1935).

Following intracerebral inoculation the virus appears in the blood after 2 to 4 days, but disappears shortly before death. The virus can be demonstrated in the cerebrospinal fluid after intranasal inoculation, but only rarely in the blood or elsewhere.

Other animals.

Field voles These animals resemble mice in their susceptibility and can be infected intracerebrally, and by intraperitoneal injection if the virus is localized in the brain by an injection of starch (Findlay and Elton, 1933). Histologically, the lesions resemble those described in mice by Hurst (*vide supra*). It should be remembered that voles live in pastures affected by louping ill, and may conceivably play some part in the spread of the disease.

Rats. Burnet (1936 *b*) has shown that rats acquire an inapparent (subclinical) infection after intranasal as well as after intracerebral inoculation (see also Greig *et al*, 1931, Lépine, 1931 *c*) No symptoms appear, but from the 2nd to 7th or 8th day after instillation the virus can be demonstrated in the olfactory bulbs These animals become immune as shown by failure of subsequent instillations to spread to the brain, and by the appearance of virus neutralizing antibodies.

Guinea-pigs and *rabbits* cannot be infected (Casals and Webster, 1944).

Other experiments.

Experiments have been conducted on the simultaneous infection of mice with louping ill and rabies, and louping ill and LGI viruses (Levaditi, 1942 *a*, *b*).

Morphology

The virus measures from 15 mμ to 20 mμ as estimated by filtration through collodion membranes (Elford and Galloway, 1933), and 27 mμ to 22 mμ as estimated by the inverted capillary tube technique (Tang, Elford, and Galloway, 1937). The eosinophilic inclusions of Hurst (1931) have already been described as occurring in mouse brain Findlay (1932) found similar bodies in monkey tissue, which, as they did not react to the Feulgen technique, may perhaps represent virus aggregates

The virus passes Berkefeld V, N, and W, Chamberland L_2 and L_3 filters (Alston and Gibson, 1931, Greig *et al*, 1931, Lépine, 1931 *b*) The virus is negatively charged at pH 7 3 (Lépine, 1931 *b*).

Cultivation

Rivers and Ward (1932–3), using chick embryo, monkey serum, and Tyrode's solution, obtained definite evidence of virus multiplication in tissue cultures of the Li and Rivers type (see also Wilson, 1945).

Burnet (1936 *a*, *b*) found the virus to be propagated readily in the developing hen egg, producing numerous foci of opacity (see also Burnet, Keogh, and Lush, 1937)

The embryo is frequently killed by the virus and appears jaundiced, but some-

tremblings, tremors, spasmodic contractions of the head and thoracic muscles, clonic or tonic convulsions, and incoordination Shortly before death, paresis of one or more limbs occurs and the animal is usually dead by the 8th to 10th day after injection.

Histologically, brains of mice dying from encephalitis show marked perivascular and diffuse lymphocytic infiltrations in the basal nuclei and cerebral cortex. In the brain stem and spinal cord acute nerve cell destruction is the most noticeable feature. There is widespread neuronophagia in the cord and the appearances closely resemble those of poliomyelitis. The cerebellum may be severely damaged with nerve cell destruction or may escape in a remarkable way

Inclusion bodies have been described by Hurst (1931); they occur in the neurons of the brain stem and cord and less commonly in the Purkinje cells and cells of the basal nuclei. They are found in the cytoplasm, as single or multiple, eosinophilic, round or oval bodies of 1 to 8 μ in diameter.

Mice can also be infected intranasally (Webster and Fite, 1932–3; Webster, 1933, Fite and Webster, 1933–4). Following such instillation virus is present in the blood from the 2nd to the 6th days, when the animals become ill (with features already described) and the virus tends to disappear. As a rule, virus is not generally present in the brain until the 3rd day, nor are histological lesions noted until the 5th day Rake (1937) has shown that the virus has reached the forebrain 24 hours after nasal instillation

Alston and Gibson (1931) noted contact infection in some of their cages, but this method of spread does not appear to have been recorded by other workers The virus can be transmitted by intrasciatic and intra-ocular injections, encephalitis developing (Lépine, 1931 *c*)

Monkeys.

The infection has been transmitted to monkeys by Hurst (1931), Findlay (1932), and Galloway and Perdrau (1935)

Some 4 to 5 days after intracerebral inoculation of virus the animal becomes less active, and shows muscular weakness and tremors, while nystagmus may occur With the progress of the infection evidences of cerebellar ataxia become noticeable, the animal is clumsy, unsteady, and bumps into obstacles Eventually the animal collapses and lies on its side Despite passing through such a severe infection recovery may occur Histologically, the cerebellar lesions are the most noticeable. There is widespread destruction and sometimes total disappearance of the Purkinje cells, but little reactionary gliosis Inclusions similar to those described by Hurst (1931) in the mouse have been described in the monkey by Findlay (1932). They occur most frequently in the neurons of the pons and midbrain and less commonly in the spinal cord and Purkinje cells The cortex, brain stem, and cord show vary-

Valley fever and louping ill viruses The viruses of louping ill and Colorado fever are unrelated (Koprowski and Cox, 1947)

The relationship to Australian X disease is discussed in Ch C.

Although differing somewhat in biological properties, louping ill virus is genically closely related to that of Russian spring-summer encephalitis, as sh by complement fixation, neutralization, and intraperitoneal cross resistance tes mice (Casals, 1944; Casals and Webster, 1943, 1944, see also Silber and Solo 1946). Russian workers claim to have isolated true louping ill virus from *Ix ricinus* ticks in White Russia (Silber and Shubladze, 1945).

There is some disagreement as to the relationship of louping ill and Ru viruses to those of Japanese and St. Louis encephalitis (see Ch. XCVIII).

[illegible] *Vet Rec.*, *11*,

times edema is present instead The liver is either deep greenish brown without necrosis, or else of normal color with extensive necrotic patches. The virus is present in the embryo blood and washed red cells from the 2nd to the 6th days after inoculation. The virus can be liberated from the red cells by treatment with distilled water. In the egg, therefore, the virus is strongly viscerotropic.

Edward (1947 *a*) has propagated the virus by inoculation in the yolk sac or embryo. The yolk sac route can be used to titrate virus suspensions or to test for virus neutralizing antibodies. The egg virus appears to [illegible] for the sheep when [illegible] in severe wintry [illegible] this was attributed to incr[illegible] the CNS, for later passage material inoculated in the summer was relatively innocuous (1947 *b*).

Serum neutralization tests can also be carried out using the pock counting method.

Reaction to Physical and Chemical Agents

The virus is heat sensitive, being destroyed at 58° C in 10 minutes, 60° C. in 2 to 5 minutes, and 80° C. in 30 seconds (Lépine, 1931 *b*).

Frozen and kept in a Petri dish in the refrigerator, the virus does not survive much over 11 to 14 days (Lépine, 1931 *b*)

The virus can be readily preserved for storage by pulping, drying *in vacuo* over sulfuric acid, and storing in the refrigerator for about 14 days. The powder is then dry and can be stored in a desiccator (Greig *et al*, 1931).

The virus can survive in glycerol for approximately 4 to 6 months (Lépine, 1931 *b*, Czardowska-Gladney and Hurst, 1931). The virus in tissue-free suspensions is rapidly inactivated by methylene blue in the presence of light (Perdrau and Todd, 1936). The virus is inactivated by bile salts, the virus-inactivating agent, saponin, sodium desoxycholate, and sodium lauryl sulfate (Burnet, Lush, and Jackson, 1939; Smith, 1939, Burnet and Lush, 1940).

Immunity Reactions in Experimental Animals

On recovery from infection, animals are resistant to reinoculation (Greig *et al*, 1931, Lépine, 1931 *c*, Findlay, 1932, Schwentker, Rivers, and Finkelstein, 1933, Galloway and Perdrau, 1935, Burnet, 1936 *b*).

Edward (1947 *b*) vaccinated mice with formolized virus in mouse brain, so that they resisted peritoneal or nasal challenge

Virus neutralizing antibodies develop in animals on recovery from infection, or after inoculations of virus by various routes in sheep, rats, monkeys, and mice Antibodies can be titrated by pock counting (Burnet, 1936 *a*, *b*), in the yolk sac (Edward, 1947 *a*), or by mouse inoculation Mixtures apparently neutral can be reactivated, and the reaction is reversible (Goyal, 1935, Burnet, Keogh, and Lush, 1937)

Complement fixation can be demonstrated between various types of brain extract and immune sera (Casals and Palacios, 1941 *a*, *b*, Casals, 1945) Casals' latest (1947) technique is described in Ch XI

Relationship to Other Virus Diseases

Although there is a certain superficial similarity in the histological appearances of poliomyelitis and louping ill, especially as regards nerve destruction and perivascular cuffing in the cord, the viruses are not closely related (Schwentker, Rivers and Finkelstein, 1933). These workers showed, first that monkeys refractory to louping ill were susceptible to poliomyelitis and vice versa, and secondly that serum neutralization tests elicited no cross reactions between the two viruses.

Findlay (1932) has shown that no cross immunity reactions occur between Rift

CHAPTER C

AUSTRALIAN X DISEASE

CLINICAL AND PATHOLOGICAL FEATURES

THE clinical features were described by a number of authors (e g, Litchfield, 1917, Cleland and Bradley, 1917; Cleland, Bradley, and Buckley, 1917, Breinl, 1917, Cleland and Campbell, 1919 *a*, *b*, 1919–20 *b*, 1920, Kneebone and Cleland, 1926).

Incubation period As in so many similar disorders it proved difficult to estimate the incubation period, but it was probably 5 to 12 days

Prodromal symptoms. These included headache, pains in the body, mental irritability or confusion, drowsiness, and weakness of the limbs.

Course. The disease was ushered in acutely (especially in children) by vomiting, fever, and convulsions. In adults the following initial symptoms were commoner. headache, neck pains, confusion, drowsiness or lethargy, muscular weakness, and incoordination

The temperature, at first 101° to 102° F., rose to 104° to 105° F. with the progress of the infection. Convulsive movements were common, especially in chil- [illegible] these movements often took [illegible] s tremors and twitchings of [illegible] were observed, and muscular rigidity was frequently present. Paralyses of eye muscles, face, or limbs were exceedingly rare The cerebrospinal fluid usually showed a well-marked pleocytosis.

The duration of the illness was usually from 10 to 12 days, after which the patient recovered rapidly. Cases proving fatal usually did so from 4 to 6 days after the onset, but in certain fulminant cases death occurred in 24 hours. The fatality rate was 70 per cent

The characteristic postmortem findings have been described by a number of authors (Breinl, 1917, Cleland, 1918–19, Cleland and Campbell, 1919 *a*, 1919–20 *b*, 1920), and have been reexamined by Perdrau (1936).

The changes were practically restricted to the nervous system, being evident in the cerebral cortex, basal nuclei, dentate nucleus of the cerebellum, the dorsal parts of the pons and medulla, and the cornua of the cord They were more pronounced in the encephalon than in the cord.

The vessels and plexuses were engorged and there were numerous petechial hemorrhages in the meninges and [illegible] in the meninges, perivascularly, [illegible]

EPIDEMIOLOGY

The epidemiological features have been fully described by Cleland and Campbell (1919 *a*, 1919–20 *a*,*b*, 1920)

In the 1917 and 1918 epidemics the country towns of New South Wales, Queensland, and Victoria were mainly involved An outbreak occurred in *1925 in* the Broken Hill district (Kneebone and Cleland, 1926).

The usual time of year for these outbreaks to occur was between January and April, with the maximum number of cases in February and March, that is to say, in the hot, dry weather

Nearly 50 per cent. of the cases occurred in individuals under 5 years of age. Males were proportionately more susceptible than females (85 56).

CHAPTER C

AUSTRALIAN X DISEASE

CLINICAL AND PATHOLOGICAL FEATURES

The clinical features were described by a number of authors (e g, Litchfield, 1917, Cleland and Bradley, 1917, Cleland, Bradley, and Buckley, 1917, Breinl, 1917, Cleland and Campbell, 1919 *a*, *b*, 1919–20 *b*, 1920, Kneebone and Cleland, 1926).

Incubation period As in so many similar disorders it proved difficult to estimate the incubation period, but it was probably 5 to 12 days

Prodromal symptoms These included headache, pains in the body, mental irritability or confusion, drowsiness, and weakness of the limbs

Course The disease was ushered in acutely (especially in children) by vomiting, fever, and convulsions In adults the following initial symptoms were commoner headache, neck pains, confusion, drowsiness or lethargy, muscular weakness, and incoordination.

The temperature, at first 101° to 102° F., rose to 104° to 105° F with the progress of the infection. Convulsive movements were common, especially in children With the deepening of lethargy and drowsiness these movements often took the form of thrashing of the bedclothes In other cases tremors and twitchings of face and limbs, teeth grinding, eye-blinking, and hiccup were observed, and muscular rigidity was frequently present Paralyses of eye muscles, face, or limbs were exceedingly rare The cerebrospinal fluid usually showed a well-marked pleocytosis

The duration of the illness was usually from 10 to 12 days, after which the patient recovered rapidly. Cases proving fatal usually did so from 4 to 6 days after the onset, but in certain fulminant cases death occurred in 24 hours The fatality rate was 70 per cent

The characteristic postmortem findings have been described by a number of authors (Breinl, 1917, Cleland, 1918–19, Cleland and Campbell, 1919 *a*, 1919–20 *b*, 1920), and have been reexamined by Perdrau (1936)

The changes were practically restricted to the nervous system, being evident in the cerebral cortex, basal nuclei, dentate nucleus of the cerebellum, the dorsal parts of the pons and medulla, and the cornua of the cord They were more pronounced in the encephalon than in the cord

The vessels and plexuses were engorged and there were numerous petechial
hemorrhages in the [illegible]

EPIDEMIOLOGY

The epidemiological features have been fully described by Cleland and Campbell (1919 *a*, 1919–20 *a*,*b*, 1920)

In the 1917 and 1918 epidemics the country towns of New South Wales, Queensland, and Victoria were mainly involved. An outbreak occurred in 1925 in the Broken Hill district (Kneebone and Cleland, 1925).

The usual time of year for these outbreaks to occur was between January and April, with the maximum number of cases in February and March, that is in the hot, dry weather.

Nearly 50 per cent of the cases occurred in individuals under 5 years of age. Males were proportionately more susceptible than females (55–56).

Some evidence of contact infection was obtained, but only rarely. An investigation was made into the possible rôle of invertebrate hosts, but no evidence was found to incriminate ticks, bugs, flies, lice, or mosquitoes Modern Australian opinion, however, would appear to hold to the possibility that the disease might have been spread by flies (see Burnet, 1934).

ISOLATION OF VIRUS FROM CASES OF X DISEASE

The main work was carried out by Cleland and his associates (see Cleland and Campbell, 1919 *a*, *b*, 1919–20 *a*, *b*, *c*, Cleland, 1918–19, Kneebone and Cleland, 1926). Breinl (1917, 1918) also isolated a strain of virus from cases of the disease by intracerebral injection of a cercopithecus monkey. These workers isolated strains in 1917, 1918, and 1925.

Animal Experiments

Monkeys. Rhesus or cercopithecus monkeys were infected by intracerebral injection. There was an incubation period of some 5 to 23 days before the animal sickened, showing dullness, lethargy, muscular weakness, incoordination, tremors, and rigidity. In 70 per cent. of animals pareses were noted. Finally convulsions might occur, the animal becoming prostrate and dying in from 2½ to 6 days

Histologically the lesions resembled those of human beings the meninges were congested and showed round cell infiltration, the brain substance was congested, the vessels showed perivascular cuffing, and there were foci of round cell infiltration There was almost total loss of Purkinje cells in the cerebellum (Perdrau, 1936).

Sheep The animals sickened after an incubation period of from 3 to 12 days The head drooped, and there were tremors, convulsions, teeth grinding, jaw champing, drowsiness, and a staggering gait.

Histologically there were perivascular cuffing and other changes as described in human cases. Destruction of Purkinje cells was not noted

Horse and calf Both these animals were infected and developed, after 5 to 9 days' incubation, convulsions, staggering, and twitchings

Insusceptible animals The infection could not be transmitted to the following animals dogs, kittens, rabbits, guinea-pigs, or fowls.

Some Properties of the Virus

The virus was not conclusively shown to pass a Berkefeld filter.

It did not survive in glycerol for over 2 months. Neutralizing antibodies developed in the sera of convalescent sheep (Cleland and Campbell, 1919–20 *b*, *c*)

RELATIONSHIP TO OTHER INFECTIONS

At the outset it was suggested that the X disease was an exalted form of poliomyelitis (Flexner, 1923) The histological pictures were, however, somewhat different, and the ease of transmission of X disease virus to horses and sheep definitely showed it to be a distinct entity. In addition, the sera of poliomyelitis convalescents proved incapable of neutralizing the virus (Cleland and Campbell, 1919–20 *c*)

At the time of the isolation of Cleland's virus the etiological agent of louping ill was unknown Inasmuch as Cleland's virus is no longer available, arguments have to be based largely on facts previously ascertained Reviews have been published by Burnet (1934) and Perdrau (1936)

No cases of louping ill in man have proved fatal (see Ch XCIX) It has not, therefore, been possible to compare sections of human material from the two diseases, one with another The brains of fatal human cases of X disease showed destruction of the Purkinje cells similar to that observed in the brains of monkeys infected with louping ill. It should be mentioned at this point that cases of widespread loss of Purkinje cells, unassociated with other lesions, have been recorded in

man, quite unconnected with louping ill or X disease (Parker and Kernohan, 1933, Greenfield, 1934).

The characteristic feature of louping ill in animals is the great destruction of the Purkinje cells that occurs, and monkeys infected with X disease showed much the same type of change. Further, the symptoms in monkeys injected are similar, although X disease produced more pareses.

To set on the other side of this question are the following facts: The symptoms in injected monkeys are not exactly the same. Neither is *Ixodes ricinus* known in Australia, nor are other species of tick common. The common ectoparasite of Australian sheep is *Melophagus ovinus*, but this remains all its life on one host (Burnet, 1934). Louping ill has never been reported in Australia, and certainly at the time no unknown disease was present in sheep in the infected localities.

It will not be possible to elucidate the matter further unless there are any more outbreaks, but the two agents are probably closely related.

CHAPTER CI

ASCENDING MYELITIS DUE TO B VIRUS

CLINICAL AND PATHOLOGICAL FEATURES

A LABORATORY worker developed a spreading infection after a bite on the hand from a monkey. He developed ascending myelitis, and died after 2 weeks (Gay and Holden, *1932–3, 1933 a, b, Sabin and Wright, 1934*)

The bite wound itself was healing well but the regional glands were hemorrhagic. Naked-eye, the brain appeared healthy, and the cord only slightly edematous The spleen was enlarged and of soft consistency. Microscopically, the change in the cord was a transverse myelitis of the mid-cervical and upper dorsal regions The medulla showed the severest lesions of any part of the central nervous system, where there was an extremely severe infiltration of polymorphs and lymphocytes, most pronounced near the floor of the 4th ventricle. Marked mononuclear perivascular cuffing was present in the pons, basal ganglia, internal capsule, and uncinate gyrus. No demyelination was noted in any part of the central nervous system. The spleen was hyperemic and showed necrotic foci, similar foci were also present in the adrenals and lymph glands Two different strains of virus were isolated.

Gay and Holden (1932–3, 1933 *a, b*) isolated W virus, and Sabin and Wright (1934) isolated B virus Sabin and Wright's work was expanded by Sabin (1934 *a, b, c*), Sabin and Hurst (1935), and Haber (1935)

CHARACTERISTICS OF B VIRUS

Infection in Rabbits

Rabbits were found to be infected readily (Sabin and Wright, 1934; Sabin, 1934 *a, b, c*, Haber, 1935). Rabbits are susceptible to intracerebral injection and die somewhat suddenly on about the 5th day. Before death, raised temperature, salivation, and convulsions may all be noted, but no paresis of the extremities

After intradermal injection, preferably in the abdomen, the virus shows a most pronounced neurotropism About 24 hours after injection erythematous papules are evident locally, and soon become hemorrhagic and necrotic centrally About the 6th day the temperature rises with the appearance of paresis of one or both posterior extremities Within another day the paralysis has spread to involve the fore limbs Seven to 12 days after injection, urinary retention, salivation, and convulsive movements of the head precede death

A fatal paralysis follows intraperitoneal, intravenous, intramuscular, intratesticular and subcutaneous injections

After corneal scarification a fatal keratitis develops, the animal can also be inoculated intranasally (Haber, 1935, Sabin, 1934 *b*)

The virus must spread to the central nervous system by the nerve trunks following peripheral injection, as after intracutaneous injection it can be found in the cord while still absent from the brain.

After intracerebral injection a comparatively mild meningitis develops, with scanty fibrinous exudate over the cerebrum and cerebellum (Sabin and Hurst, 1935).

At the *site of injection* in the cortex there is some slight necrosis of nerve cells [illegible] inclusions are found in the glial cells The [illegible] l and subependymal glia, and in the cortical [illegible] cortical vessels is noted

After intracutaneous [illegible] *hemorrhagic necrotic lesion* forms locally

There is extensive necrosis of the cutis and subcutaneous tissues with infiltration by polymorphs and mononuclears. At the periphery of the lesion typical inclusions are to be found. Spread of the infective process occurs and degeneration and polymorph infiltration can be demonstrated in the appropriate spinal ganglia. Next, the corresponding segments of the cord are involved by severe degenerative and inflammatory reaction, converting the tissue into a diffluent mass Inclusion bodies are found in the nerve cells and glia before the appearance of these changes. Rabbits injected intracutaneously, as well as by other peripheral routes, show lesions in the internal organs

After intramuscular injection a severe necrosis of muscle cells, vessels, and nerves occurs The sciatic nerve shows an interstitial neuritis while inclusions are present in the connective tissue cells and the sheath of Schwann.

After intravenous injection necrotic foci are present in the adrenal and less commonly in the liver and spleen

After intraperitoneal injection foci of necrosis can be found in the adrenal, liver, spleen, and ovary.

Monkeys.

The virus is pathogenic for *M rhesus* and cebus monkeys Callithrix monkeys can be infected also, but not cynomolgus (Haber, 1935)

After intracerebral inoculation, paresis, rigidity, and incoordination develop and death frequently follows

After intravenous injection an eruption appears on the forehead, conjunctivae, face, tongue, and buccal mucosa

Intracutaneous injection is followed by an acute hemorrhagic and necrotic lesion, again resembling a vaccinial pock

Intraperitoneal injection results in the development of peritonitis.

Pathology of infected monkeys (see Sabin and Hurst, 1935)

After intracerebral injection, as contrasted with rabbits, a gross meningitis develops, the pia over the cortex, stem, and cerebellum being infiltrated with fibrinous exudate in which are polymorphs and mononuclears Inclusions are to be found in the meningeal vessel cells as a prelude to necrosis The adventitial and muscular coats are frequently severely affected by this degenerative process The site of inoculation is involved in a hemorrhagic [illegible]

[illegible]

[illegible] and loss of Nissl bodies, some infiltration with polymorphs and proliferation of glia are usually present After peripheral injection in monkeys the nervous lesions are very mild, but focal necroses may be found in the liver, spleen, adrenal, and ovary

Other animals.

Guinea-pigs [illegible] bral injection fatal [illegible] do not occur, but [illegible]

Mice develc [illegible]

Certain Other Properties of B Virus

Elementary bodies have not been described, although inclusion bodies have been found (Sabin and Hurst, 1935). These bodies are intranuclear, and occur in cells in the central nervous system and internal organs They resemble closely the inclusions of herpes, pseudorabies, virus III, and salivary gland virus of guinea-pigs It has been proved possible to demonstrate the inclusions of B virus in superinfected Shope's papillomatous tumors in rabbits (Syverton and Berry, 1947*a*), the inclu-

Microscopically, the change in the cord was a transverse myelitis of the mid-cervical and upper dorsal regions The medulla showed the severest lesions of any part of the central nervous system, where there was an extremely severe infiltration of polymorphs and lymphocytes, most pronounced near the floor of the 4th ventricle Marked mononuclear perivascular cuffing was present in the pons, basal ganglia, internal capsule, and uncinate gyrus No demyelination was noted in any part of the central nervous system The spleen was hyperemic and showed necrotic foci, similar foci were also present in the adrenals and lymph glands Two different strains of virus were isolated.

Gay and Holden (1932–3, 1933 *a*, *b*) isolated W virus, and Sabin and Wright (1934) isolated B virus. Sabin and Wright's work was expanded by Sabin (1934 *a*, *b*, *c*), Sabin and Hurst (1935), and Haber (1935).

CHARACTERISTICS OF B VIRUS

Infection in Rabbits

Rabbits were found to be infected readily (Sabin and Wright, 1934, Sabin, 1934 *a*, *b*, *c*, Haber, 1935). Rabbits are susceptible to intracerebral injection and die somewhat suddenly on about the 5th day Before death, raised temperature, salivation, and convulsions may all be noted, but no paresis of the extremities

After intradermal injection, preferably in the abdomen, the virus shows a most pronounced neurotropism About 24 hours after injection erythematous papules are evident locally, and soon become hemorrhagic and necrotic centrally About the 6th day the temperature rises with the appearance of paresis of one or both posterior extremities Within another day the paralysis has spread to involve the fore limbs. Seven to 12 days after injection, urinary retention, salivation, and convulsive movements of the head precede death.

A fatal paralysis follows intraperitoneal, intravenous, intramuscular, intratesticular and subcutaneous injections

After corneal scarification a fatal keratitis develops, the animal can also be inoculated intranasally (Haber, 1935, Sabin, 1934 *b*).

The virus must spread to the central nervous system by the nerve trunks following peripheral injection, as after intracutaneous injection it can be found in the cord while still absent from the brain

After intracerebral injection a comparatively mild meningitis develops, with scanty fibrinous exudate over the cerebrum and cerebellum (Sabin and Hurst, 1935)

At the site of injection in the cortex there is some slight necrosis of nerve cells and numerous eosinophilic intranuclear inclusions are found in the glial cells The inclusions are widespread in the subpial and subependymal glia, and in the cortical nerve cells. Mononuclear cuffing of the cortical vessels is noted

After intracutaneous injection a hemorrhagic necrotic lesion forms locally.

paresis of the lower extremities Intranuclear inclusions are readily found, and in Ammon's horn involve nearly every cell After intradermal injection, the results are similar to those obtained with B virus, an ascending paresis following a local hemorrhagic and necrotic lesion

Rhesus monkeys cannot, but cebus monkeys can, be infected on intracerebral injection, the animals dying in 7 days after showing spastic paresis, lethargy, and convulsions.

Gay and Holden regarded the properties of W virus and of herpes as identical However, the results on intradermal injection of rabbits with W virus resemble exactly those of B virus, and are more pronounced than in the case of herpes

To confirm their view, these authors undertook some cross immunity tests with Perdrau's E L.1 strain of herpes Among other experiments they found that antiherpetic rabbit serum modified but did not completely neutralize W virus. They came to the final conclusion that W virus was a strain of herpes

CONCLUSIONS

It appears that B and W viruses are identical, and this virus, although closely related to herpes, is probably distinct.

In our opinion, it is most probable that the infection was transmitted by the monkey, even though Haber (1935) has not been able to demonstrate the virus in a number of specimens of saliva The virus has unusual properties, differing from the common type of herpetic strains, and in all probability may be normally carried by monkeys in captivity, especially as Sabin, and Burnet, Lush, and Jackson (1939 *b*) found antibodies in monkey sera

sions of vaccinia and B virus have been demonstrated in the cytoplasm and nucleus respectively of individual cells of the rabbit cornea (1947 *b*).

As regards filtrability, the virus passes through a Berkefeld V and N, a Chamberland L_3, and a single disk Seitz (Sabin and Wright, 1934; Sabin, 1934 *b, c*).

It is deposited in 3¼ hours at 14,000 r.p.m. (Sabin, 1934 *b*)

The virus resists glycerol for at least several months. It is sensitive to the virus-inactivating agent in normal human nasal secretion which acts powerfully on influenza virus, it is also inactivated by saponin, sodium desoxycholate, and sodium lauryl sulfate (Burnet, Lush, and Jackson, 1939 *c*; Burnet and Lush, 1940).

Shocking doses of metrazol or insulin did not influence the course of infection in adult mice (Holden, 1940). B virus produces pocks on the chorio-allantois (Burnet, Lush, and Jackson, 1939 *a, b, c*).

Relationship to Herpes

Resemblances can be recapitulated as follows. (*a*) development of encephalitis in rabbits after intracerebral or corneal inoculation of virus, the 2 histological pictures being very similar, (*b*) development of adrenal necrosis after intravenous injection of rabbits, (*c*) production of myelitis after intradermal injection of rabbits (note, however, this is much commoner with B than herpes); (*d*) similar intranuclear inclusions, (*e*) similar effect on cebus monkeys

There are, however, certain differences Thus, after intratesticular injection, myelitis develops with B, but encephalitis with herpes. Rhesus monkeys are susceptible to B only. After intravenous injection necrotic lesions of the spleen and liver only occur with B It appears to us that these differences, although only in degree, are sufficient justification for regarding B virus as a distinct entity. This claim is further strengthened by the following cross immunity reactions carried out by Sabin. Herpes-immune rabbits generally succumb from an intradermal injection of B virus, but occasionally a small dose may prove noninfective In support of this it was found that herpes-immune sera (guinea-pig) are usually quite inactive against B virus but rarely may neutralize a minimal dose, vice versa, immune B sera may neutralize a minimal dose of herpes

This problem has been investigated by Burnet, Lush, and Jackson (1939 *b*), by the chorio-allantoic technique They found antibody to B virus in the sera of Australian monkeys, and showed that these sera inactivated herpes to a comparable titer. The inoculation of monkeys with B resulted in the appearance of antibodies which were considerably more active against herpes than B virus They concluded that, as demonstrated by the egg technique, B is a more complete antigen than herpes virus.

Relationship to Pseudorabies and Other Viruses

Cross immunity reactions (Sabin, 1934 *c*) have been carried out Briefly, anti-B sera may neutralize minimal amounts of pseudorabies, guinea-pigs convalescent from B infection may resist minimal doses of pseudorabies, and one monkey solidly immune to B was found to be resistant to pseudorabies It appears, then, that the relationship to pseudorabies is of the same order as that to herpes B virus is allied but distinct.

Cross immunity tests with neutralizing antisera or immune animals failed to show any relationship to equine encephalomyelitis, virus III of rabbits, or vaccinia (Sabin, 1934 *c*). The virus of feline agranulocytosis is not related (Lawrence *et al*, 1943).

W VIRUS

Gay and Holden (1932–3, 1933 *a, b*) obtained a very similar virus from the same fatal case They were able to transmit the infection to rabbits by intracerebral injection The animals die after 4 to 6 days with fever, salivation, tremors, and

paresis of the lower extremities Intranuclear inclusions are readily found, and in Ammon's horn involve nearly every cell. After intradermal injection, the results are similar to those obtained with B virus, an ascending paresis following a local hemorrhagic and necrotic lesion

Rhesus monkeys cannot, but cebus monkeys can, be infected on intracerebral injection, the animals dying in 7 days after showing spastic paresis, lethargy, and convulsions.

Gay and Holden regarded the properties of W virus and of herpes as identical However, the results on intradermal injection of rabbits with W virus resemble exactly those of B virus, and are more pronounced than in the case of herpes.

To confirm their view, these authors undertook some cross immunity tests with Perdrau's E L 1 strain of herpes Among other experiments they found that antiherpetic rabbit serum modified but did not completely neutralize W virus They came to the final conclusion that W virus was a strain of herpes

CONCLUSIONS

It appears that B and W viruses are identical, and this virus, although closely related to herpes, is probably distinct.

In our opinion, it is most probable that the infection was transmitted by the monkey, even though Haber (1935) has not been able to demonstrate the virus in a number of specimens of saliva. The virus has unusual properties, differing from the common type of herpetic strains, and in all probability may be normally carried by monkeys in captivity, especially as Sabin, and Burnet, Lush, and Jackson (1939 *b*) found antibodies in monkey sera

CHAPTER CII

INFECTIVE HEPATITIS

CLINICAL FEATURES

Adults.

William Stokes (1839) of Dublin, is credited with having recognized that jaundice was due to a mild form of hepatitis.

After an incubation period of about 30 days (see p. 1169) the disease commences with a history of malaise, anorexia, weakness, upper abdominal discomfort, bodily aches and pains, vomiting, and headache with low fever up to 103° F. usually lasting for about 5 to 7 days, or at times as long as 3 weeks. This is followed by the stage of jaundice of varying intensity, necessitating hospital care for a fortnight to 3 months, depending on the severity of the attack In mild cases, jaundice disappears in 2 weeks, and in the severest after 8 weeks In addition to the well known description of Cameron (1943) the earlier accounts of Blumer (1923), Pickels (1936–1942), and Cullinan (1939) should be consulted.

A summary of the signs and symptoms observed in 260 cases of hepatitis with jaundice has been provided by Zimmerman, Lowry, Uyeyama, and Reiser (1947). Over half the cases complained of symptoms of anorexia, dark urine, malaise, nausea, ocular pain, chilly sensations, headache, fever, and epigastric discomfort, and the remainder of vomiting, heartburn, constipation, pruritus, alternate constipation and diarrhea, respiratory discomfort, chills, diarrhea, clay-colored stools, and dysuria.

Clinical signs elicited in over half these cases were jaundice affecting both skin and sclera, usually tenderness of epigastric region, enlarged liver and adenopathy of generalized or cervical distribution. Less than 50 per cent. displayed splenomegaly, bradycardia, fever, rash, and herpes labialis During the icteric stage of the illness, Kirk (1947) reported that mild mental depression was not uncommon but during prolonged icterus confusional states were prone to ensue Cerebral manifestations, persistent vomiting and ascites are prognostic signs of evil significance according to Lucké (1944)

Children.

The disease tends to pursue a milder course Anorexia, vomiting, diarrhea, and abdominal discomfort are of shorter duration than in adults and severe hepatitis with prolonged icterus and long convalescence are unusual. (See Cockayne, 1912, Cullinan, 1939, Evans, 1942, Ford, 1943, Lisnev, 1944, Horstmann, Havens, and Deutsch, 1947.)

In England, biochemical tests on child contacts showed that infection may occur in the complete absence of icterus (Pollock, 1945 *b*) Similar observations were made at New Haven, by Horstmann, Havens, and Deutsch (1947) who commented upon the mildness of symptoms, their short duration, and the difficulty in persuading children to remain in bed.

Neurological complications Four varieties of nervous lesions have been described, all of which were believed to be due to the effects of chemical toxic absorption from the gut, resulting from liver dysfunction The first of these were

general in character, namely, coma, delirium, convulsions, and incontinence Secondly, there were striatal and pyramidal lesions characterized by increased tendon reflexes, clonus, and muscular rigidity with extensor plantar responses, occasionally with choreiform movements and parkinsonian tremor. The third group showed massive hemorrhages into caudate nucleus and subdural hematomata, and the last, peripheral neuritis (Stokes, Owen, and Holmes, 1945)

Mortality Whether cases be epidemic or sporadic the mortality is low. Lucké (1944) states that the rate in the United States Army outbreak of 1942 was 0 44 per cent For the Civil War, World War I, the German Navy (between the years 1919 and 1929), the Finnish outbreak of 1933, 1936, and the later Swedish epidemics the mortality ranged from 0 13 to 0 44 per cent.

PATHOLOGY

Clinical Pathology.

A good account is given by Zimmerman, Lowry, Uyeyama, and Reiser (1947).

Icteric index. Case values ranging from as low as 10 to as high as 180 have been recorded, the former case took about 7 days to return to normal and the latter 58 days No plateau was observed, that is, the peak was quickly reached and thereafter recession was prompt

Blood count. There was a tendency toward reversal of the lymphocyte leukocyte ratio and a slight eosinophilia (see also Havens and Marck, 1946).

Serum proteins. Using the copper sulfate method 81 severe cases showed serum [illegible] rsal of the [illegible] gh (Westergren) rate of 10 to 30 mm per hour encountered in a case of 4 to 8 weeks' dura- [illegible]

[illegible] flocculation, the hippuric acid excretion, the galactose tolerance, the bromsulfthalein excretion, and the thymol turbidity reaction (see Pollock, 1945 *a*, Dick, 1945, Kunkel and Hoagland, 1946, Makari, 1946).

In children increa[illegible] ported by Rapoport [illegible] of jaundice is claimec [illegible] protein reactions see Bjørneboe (1946 *a*). *X-ray and gastroscopic* examination of cases showed that acute gastritis was an early lesion of the disease (Havens, Kushlan, and Green, 1947)

Morbid histology of liver in biopsy specimens.

The early investigations of Iverson and Roholm (1939) showed that a small cylindrical biopsy specimen of the right lobe of the liver could be extracted with the aid of a 2 mm bore cannula passed transpleurally under local anesthesia. The operation is by [illegible] rhage and is, th [illegible]

The above s[illegible] Sherlock (1945) who obtained 61 such biopsy specimens from 14 cases of infective hepatitis, 35 of arsenotherapy jaundice, and 7 of serum jaundice No histological differential criteria could be recognized between any of the above conditions and

Dible, McMichael, and Sherlock (1943) are quoted thus: "A hepatic inflammation of varying intensity and distribution is common to them all, and, therefore, for purposes of pathological description, we may disregard this etiological grouping and consider the findings as a whole. The changes in the liver are related to the severity and duration of the disease. For purposes of comparison we have dated the condition from the onset of jaundice although there is always a variable period of diverse prodromal symptoms." These authors give the following account of the histology

Broadly speaking, the picture is one of hepatic cell necrosis and autolysis, associated with leukocytic and histiocytic reaction and infiltration The centers of the lobules show the first of these changes most markedly, and the portal tracts the greatest cellular infiltration In certain cases, which seem to be either those which are mild *from the beginning or in which the lesion is retrogressing, the periportal* cell accumulations predominate in the picture, in contradistinction to the more severe cases in which hepatic cell degeneration is more pronounced and the histiocytic and leukocytic infiltration more widespread For descriptive purposes we call the first of these the "zonal" and the second the "diffuse" type of change, but it must be understood that there are no good reasons for regarding these differences as fundamental, and that an intermediate picture occurs which has been denominated a "mixed" lesion. Finally, there are those cases in which the lesion is well on

[illegible] necrosis, nodular
[illegible] very significant
[illegible] the pathological

picture. Several of the cases seem to have been verging on acute liver necrosis—12 out of 56 cases showed histological damage of more than 50 per cent. of liver cells —yet the normal course is to complete recovery. Fatal or permanent damage is rare. Lucké (1944) also mentioned that there was no evidence of residual damage following recovery from infective hepatitis.

The frequency with which a periportal "cirrhosis-like" picture is encountered leaves little doubt that it constitutes one pathological form of acute hepatitis. Roholm and Iversen (1939) also noted this appearance, but were uncertain whether it represented a long-standing hepatitis with jaundice resulting from an acute exacerbation. That acute and subacute necrosis and cirrhosis could follow epidemic hepatitis has been recognized previously (Bergstrand, 1930, Cullinan, 1936, Krarup and Roholm, 1941).

Jaundice persisting over 2 weeks is more likely to be due to a zonal lesion Diffuse hepatitis usually heals completely and rapidly. When the disease runs a longer course some residual fibrosis in the portal zones may still be present after apparent clinical cure. There is no evidence that there is a form of jaundice due to duodenal catarrh and obstruction of the common bile duct by mucus (see also van Rooyen and Gordon, 1942).

Mechanism of icterus production.

Dible, McMichael, and Sherlock (1943) have provided the following explanation which we quote verbatim "The mechanism of production of icterus is a matter of some interest The disruption of the liver-cell columns with their inter-cellular bile canaliculi may create a form of obstruction to bile flow The isolation of liver cells may also lead to the excretion of bile into the surrounding tissue spaces It is also obvious that the degree of damage may be such that the surviving liver cells are quantitatively inadequate to excrete the bile pigment brought in the blood stream Histologically, pigmented cells are seen, especially at the center of the lobule Some of these are obviously necrotic, while others have lost their glycogen The latter may accumulate bile because they are unable to excrete it, while the former become pigmented in consequence of their death The affinity of dead tissue for bile is a common pathological phenomenon. Further out in the lobule

we meet with "bile thrombi," the finest intercellular canaliculi being filled

Damodaran and Hartfall, 1944)
Africa and the landing of British

(Sawyer *et al*, 1944
Hanlon, 1946) The "boom" or "oil" towns in the

Alberta, Canada, were attacked in 1941 and 1942 (Somerville and Clark, 1944). Probably thousands of cases occurred in Great Britain, Stocks (1944) alone reported *4,100 cases from January, 1942, to June, 1943, and many others* were reported by Follows (1940), Ford (1943), Edwards (1943), and Cookson (1944). Lisney (1944) reported 1,062 cases in Leicestershire, nearly half of which affected children of 5 to 10 years of age. In the Mariana Islands of the Pacific Ocean, a division of American Marines who entered combat on June 15th, 1944, first on Saipan and later Tinian, suffered [illegible] l of Ceylon was affected (Jayaw [illegible]).

On [illegible] the Scandinavian countries by Wickstrom (1940), Selander (1939), and Hallgren (1943), from Denmark by Bjørneboe (1946 *a*, *b*); and 600 cases from the German-Russian fighting front by Jacobi, Kreyenberg, and Dörschel (1943). For further data on the incidence of infection in the German-Italian Armies see Dietrich (1942), Gutzeit (1942), Siegmund (1942), and von Bormann *et al* (1943). Leningrad was affected in 1942 and 1943 (Viskovsky, 1944).

The above references describe reported outbreaks over a wide area of the globe, but it can be assumed that during the war years, 1941 to 1944, infective hepatitis was world-wide in distribution. With the cessation of hostilities and the dispersal of troop concentrations its incidence has declined.

EPIDEMIOLOGICAL CHARACTERS

Within and without the armed forces, World War II provided unique opportunities for study of the relative susceptibility of different social, economic, and racial strata of individuals to infective hepatitis Much has been written but relatively little is understood.

Racial susceptibility.

In the armed forces, the disease appeared to affect young soldiers, principally those of European stock, on active service abroad, the highest incidence probably was recorded in the Mediterranean theater of operations In Egypt, whereas United Kingdom, New Zealand, Australian, American, and certain South African soldiers were readily infected, there was reason to believe that the case rate was lower among troops who hailed from other parts of the British Commonwealth. In December, 1942, some 15 per 1,000 contracted jaundice in General Montgomery's famous Desert Eighth Army (Spooner, 1944) and during the earlier month of October 35 2 per 1000 suffered from it in the Second New Zealand Expeditionary Force, but Kirk (1947) commented that the 28th Maori Battalion and the Indian troops who served with this Army were only very lightly affected Likewise although the condition was prevalent among British personnel of General Headquarters and other military base establishments, centered around the outskirts of Cairo, there was a conspicuous absence of cases among local adult Egyptians (van Rooyen and Kirk, 1946) Similar observations were made regarding the disparity in case incidence between the military and civilian populations of Palestine (Cameron, 1943) This feature was still more obvious in the island garrison of Malta where the attack rate was 13 7 per 1000 in British soldiers, 0 24 per 1000 among locally enlisted Maltese and apparently no epidemic was noted among Maltese civilians (Dixon, 1944). Supplementary evidence to support these claims was furnished by Kligler, Btesh, and Koch (1944) who pointed out that each successive group of newly arrived European Jewish immigrants to Palestine, especially children, was vulnerable to attack. In Ceylon, relatively few local Ceylonese troops were admitted to hospital [illegible] French Arab troops serving in Italy sh [illegible] o Gauld (1946) but the Brazilian [illegible] autumn and winter of 1944–45 seemed to escape

Social class selection.

It was noticed in Egypt that British Army Officers, as a class, were about 4.7 *times* as susceptible to attack as other ranks (Spooner, 1944). Similar epidemiological field studies in N Africa and Italy among American Forces by Gauld (1946) revealed that the officer : other rank, attack rate ratio, varied in different types of [illegible]

Effect of seasoning.

Gauld (1946) showed that for a single period in a total of 3 regiments in troops who had lived through a previous epidemic the attack rate was 39 7 per 1000 against 108 7 per 1000 for reinforcements. During 1944–5 in 6 divisions of General Eisenhower's Fifth Army the highest rates were returned from units receiving the largest reinforcements.

Seasonal incidence.

In Egypt, the months of August and September showed the greatest number of cases (van Rooyen and Kirk, 1946), but in America and elsewhere cases may occur throughout the whole year (Havens, 1946 *a*) and the reasons for such variation is not known. It is not improbable that if sanitary conditions are very bad at any place the disease may break out

Incubation period.

Under natural conditions, the interval between the calculated day of exposure to infection and onset of jaundice has been estimated to be a minimum of 32 days by Cameron (1943) But if the date of onset of symptoms prior to icterus is accepted then the period may be taken as 20 to 40 days with an average of 28. The period for the disease experimentally induced by feeding icterogenic serum or heavily infected feces, may range from 16 to 85 days and is usually about 25 days, according to Havens (1946 *a*) MacCallum and Bradley (1944) found the time to be 27–31 days. Wide variation in the incubation period encountered by *different* workers hints at the existence of multiple strains of virus, varying in virulence Gradations in individual susceptibility of different batches of volunteers to infection may also be an important factor

In an interesting experiment Francis, Frisch, and Quilligan (1946) showed that blood obtained from an incipient case of infective hepatitis and inoculated intravenously in a volunteer elicited the first symptom in 11 days and jaundice in 21. They were also able to demonstrate that the virus of infective hepatitis was present in blood of the recipient on the 8th day after transfusion, *namely*, 3 days before the first symptom of illness, as well as 3 days after it and 13 days before jaundice appeared In 4 subjects, the incubation period varied from 42 to 47 days and likewise the clinical severity Francis and his coworkers point out the difficulty of attempting to classify infective hepatitis on the basis of incubation period after parenteral injection of icterogenic serum. Furthermore, they *are not convinced* that the dose of virus is totally unrelated to the clinical severity of the resulting disease as popularly thought Finally, most important of all, they point out that the occurrence of virus in blood well before the onset of infective hepatitis, may result in its transmission by blood products derived from individuals in whom the presence of virus would be entirely unsuspected

Subclinical attacks.

Adults. It is possible that missed cases of the disease may play an integral part, in the dissemination of infection Clinical observations in the isolated garrison of Malta by Dixon (1944) and in N. Africa by Hunt (1944), have emphasized this aspect.

ETIOLOGY

According to Migne (1844), the contagious character of jaundice is said to have been referred to in a letter from Pope Zacharias A.D. 741–752, to Boniface (Wynfrith) the apostle of Germany, concerning cases among Germans.

Little is known of the causal agent of infective hepatitis although it is generally accepted to be a virus. Thus, failure to isolate a specific pathogenic cultivable bacterium from blood, feces, or urine, plus the fact that the condition can be transmitted, in man alone, by parenteral inoculation of bacteriologically sterile filtered serum or ingestion of feces, amount to the sum total of evidence upon which the icterogenic agent has been classified as a virus For a comprehensive account of human experimental studies see Paul, Havens, Sabin, and Philip (1945).

Distribution of virus in man.

Virus is present in the serum and whole blood of established jaundiced cases of the natural disease (Cameron, 1943), and in feces (MacCallum and Bradley, 1944; Havens, Paul, van Rooyen *et al.*, 1945). Volunteers fed with feces showed virus in their stools on the 5th day of illness prior to the onset of jaundice, but by the 25th day virus had disappeared from stools Pooled stools from convalescent cases on the 25th and 29th days were noninfective to volunteers Similar tests with serum [illegible]

[illegible] tained virus A summary of human experiments appears in Table 40

Properties of the virus.

Filtrability The agent has been shown to pass the Mandler filter under 9 lbs pressure per square inch (Francis, Frisch, and Quilligan, 1946), the Chamberland No 2 filter (Havens, 1945 *a*), and Seitz filter by Neefe and Stokes (1945).

Heat It is unaffected by exposure to 56° C for 30 minutes (Havens, 1945 *a*).

Cold. Like other viruses, the agent can be preserved at low temperatures in CO_2 ice (at −70° C.) for 8 months (Havens, Ward, Drill, and Paul, 1944).

Chemicals. In contaminated water, one part per million residual chlorine failed to inactivate the virus (Neefe, Stokes, Baty, and Reinhold, 1945), but if water was treated with coagulation, filtration, and settling, then inactivation occurred (Neefe *et al*, 1947)

Cultivation The virus has not been cultivated in the embryonated egg, and claims to have transmitted it to animals have lacked confirmation, likewise, reports concerning the presence of elementary bodies in infected tissues are lacking.

Therapeutic effect on rheumatoid arthritis.

MacCallum and Bradley (1944), claimed that cases of this disease were improved by an artificially induced attack of infective hepatitis Relapses of arthritis have been reported by Rennie and Fraser (1946)

Mode of Spread

Infection is almost certainly conveyed by the alimentary tract (Willcox, 1916). Blumer (1923) also suggested that infectious jaundice in the United States may be spread by the oral route.

Water. In the light of modern knowledge, an early description of a unique outbreak of infective hepatitis which affected students at Mount Allison University in Sackville, New Brunswick, Canada, in December, 1930, and January, 1931, which was investigated with great thoroughness by Fraser (1931) makes interesting reading Fraser (1931) studied 173 cases of "catarrhal" jaundice which he found was preceded by an [illegible]
be infectious b [illegible]
was excluded [illegible]
water was bla [illegible]
(1931) failed to isolate any pathogenic bacterium or leptospira from the suspected water and that the high level of *Salmonella schottmulleri* agglutinins in human sera [illegible] sanitation. For details of a recent case of [illegible] idary invasion with *Salmonella*, see Havens [illegible], N. Sweden, Hallgren (1943) reported an epidemic which appeared to be of water-borne origin. Another outbreak of water-borne origin has been reported by Neefe and Stokes (1945) at a summer camp for children Apparently the girls' drinking water well aroused suspicion because it was

Subclinical attacks.

Adults. It is possible that missed cases of the disease may play an integral part, in the dissemination of infection. Clinical observations in the isolated garrison of Malta by Dixon (1944) and in N. Africa by Hunt (1944), have emphasized this aspect.

ETIOLOGY

According to Migne (1844), the contagious character of jaundice is said to have been referred to in a letter from Pope Zacharias A.D. 741–752, to Boniface (Wynfrith) the apostle of Germany, concerning cases among Germans.

Little is known of the causal agent of infective hepatitis although it is generally accepted to be a virus Thus, failure to isolate a specific pathogenic cultivable bacterium from blood, feces, or urine, plus the fact that the condition can be transmitted, in man alone, by parenteral inoculation of bacteriologically sterile filtered serum or ingestion of feces, amount to the sum total of evidence upon which the icterogenic agent has been classified as a virus. For a comprehensive account of human experimental studies see Paul, Havens, Sabin, and Philip (1945).

TABLE 40

Zealand soldiers From the results of statistical analysis, by comparing the incidence of cases in front and rear line troops and after eliminating food, water, mosquitoes, and other obvious factors, Kirk (1945) concluded that the outbreak among the New Zealanders was fly-borne in character. The ground held by NZEF had been recaptured from the enemy, it was grossly polluted with feces and imperfectly buried corpses, flies were innumerable and sanitation extremely bad. During the period under review on the Alamein line at the time of the Battle of Ruwyeisat Ridge, fought on July 14th, 1942, the wind blew from the enemy lines across "no man's land" on to the defended front, carrying with it swarms of flies and the odor of decomposing bodies, a scene repugnant to eye and nostril. So bad were the flies that it was impossible to protect food from them and many preferred to eat after dark and before dawn. Another account of the fly menace in the Western Desert was provided by Richmond and Gear (1945) who wrote that after the retreat from Gazala to El Alamein, flies assumed the proportions of a plague

Urine.

Although Findlay and Willcox (1945) successfully infected volunteers by feeding urine, the work has not been repeated (Paul and Havens, 1946)

Rats.

These have been suspected to play a part in the dissemination of infection at Leningrad by Viskovsky (1944)

Summary of evidence.

Infective hepatitis is a disease of communal living and communal feeding During wartime it flourishes in camps and armies, and in peacetime in civilian institutions, where amenities for the maintenance of personal hygiene, ablution, laundry, and cleaning services are restricted

Immunity Phenomena in Infective Hepatitis

It is not improbable that immunity to this disease may be more widespread among nations and communities than generally supposed, and that such resistance may frequently result from unrecognized subclinical attacks Thus, Stokes and Neefe (1945) showed that human gamma globulin derived from healthy blood donors contained neutralizing antibodies which, when administered to infected human volunteers in the incubation period, was capable of preventing or attenuating the onset of infective hepatitis (see also Gellis *et al*, 1945 *a*, *b*, and Havens and Paul, 1945) It has also been shown by Neefe, Stokes, and Gellis (1945) and Havens (1946 *d*) that one attack of experimentally induced infective hepatitis confers immunity against a second attack of the same agent possibly for many months

Second attacks.

During large epidemics, these are relatively uncommon Experimental work (Havens, 1946 *d*) on man also suggests that a single attack of infective hepatitis provides immunity against the same strain of virus, but Havens (1946 *a*) has declined to answer the question whether such immunity conferred resistance toward multiple strains of virus Chronic hepatitis in the Mediterranean area has been reported by Barker, Capps, and Allen (1945), the etiology of which is obscure.

Cross immunity with serum jaundice.

Evidence is conflicting, but it is probable that no cross immunity exists between the 2 diseases One attack of serum jaundice does not protect against subsequent attacks of infective hepatitis according to Havens (1945 *b*) but Oliphant (1944)

surrounded at a distance of *75 to 180 feet by 4 cesspools which received* sewage from the girls' cabins. Five volunteers each drank 7000 c.c. of water from this well and 61 to 78 days later all 5 men developed symptoms of hepatic dysfunction.

Food The source of an explosive outbreak occurring at a university students' club was narrowed down to infection acquired from food taken on one or two days (Read *et al.*, 1946).

Milk. Milk has been blamed for an outbreak of 10 cases affecting a group of 144 persons living in 26 homes at Georgia who received milk from the same dairy.

Droplet infection.

Epidemiological studies by workers in Britain (Edwards, 1943), in the Marianas (Getty, 1946), and studies on troops who had returned to Britain from Sicily (McFarlan, 1945) suggest that the disease is disseminated by close contact droplet infection These observations were not confirmed by Spooner (1944) who studied the major 1942 epidemic of infective hepatitis affecting British troops in Egypt, Palestine, and the western desert. Spooner (1944) stated that 2 observations were inconsistent with a droplet spread. One was that there was no tendency for more than one case to occur in a vehicle crew stationed in a lonely desert outpost, and when a second case did develop it usually happened within a fortnight of the first The other objection was that the disease failed to spread in prisoner of war camps, where infected new arrivals did not appear to infect their comrades and pen mates who had been taken earlier. To this, the authors would add that despite the bomb damage and gross post-war domestic overcrowding prevailing in Great Britain today, the incidence of infective hepatitis has decreased and not increased as may have been anticipated, if droplet infection is the customary method of spread.

To date, all efforts in the United States to demonstrate the virus of infective hepatitis in nasopharyngeal washings have failed (Paul and Havens, 1946).

Fecal contamination.

Infective hepatitis has so frequently been reproduced in human volunteers (see Table 40) by feeding infected stools, that it requires little imagination to conjecture how the disease could spread in countries such as Egypt where the general standard of sanitation is not high and even cholera may occur, as it did in 1947 The resistance of infective hepatitis virus to heat, drying, and such antiseptics as chlorine, reveal the potentialities of this virus as an agent capable of causing massive infection among insanitary communities.

van Rooyen would like to quote 5 interesting cases brought to his notice by fellow officers in 1942 and 1943, where the circumstances aroused suspicion that the disease was one transmitted by fecal contamination and fomites The first was that of a young soldier suffering from severe gunshot injuries to the spine, with resulting paraplegia and incontinence of urine and feces This man was sponged daily and tended by 2 full-time army nurses Shortly after admission he developed jaundice and a month later both nurses likewise contracted infection. There were no other cases among the nursing staff at the time

The second instance occurred when 2 men attached to a large base depot quartermasters store suddenly developed jaundice in the month of June, 1943, at a time when no other cases existed in the unit Inquiries revealed that both men had been occupied in sorting out and handling the soiled battle dress clothing of New Zealand soldiers who had been killed in action

Flies Kirk (1947), whose experience of this disease in the field is unsurpassed, studied 1,500 clinical cases admitted to the wards of the First New Zealand General Hospital between September and December, 1942 He also conducted first hand epidemiological studies in the Western Desert when serving with the Second New Zealand Expeditionary Force attached to the Eighth Army between July, 1942, and January, 1943, when 2,095 cases occurred among some 15,000 front line New

CHAPTER CIII

HOMOLOGOUS SERUM JAUNDICE

An icterogenic agent, presumably a virus, is now recognized to occur in the serum of a proportion of apparently healthy individuals The parenteral administration of blood, plasma, or serum from such persons by syringe and needle, whether for the prevention of measles, mumps, sandfly fever, for blood transfusion, or through the

responsible for much

with those of infective hepatitis Moreover, the properties of these two etiological agents are so very similar that serum jaundice virus may be a variant form of infective hepatitis It is also important to remember that some examples of apparent "serum jaundice" may represent artificially induced infective hepatitis, although all serum jaundice may not be due to this cause (Paul and Havens, 1946) Both conditions are species-specific for man, and, notwithstanding the generosity of volunteers in America, Britain, and Europe who have cheerfully submitted to experimentation at the risk of serious liver injury and death, wide gaps exist in the state of medical knowledge of the pathogenicity of these agents

Clinical Features

The signs and symptoms of serum jaundice are indistinguishable from those of infective hepatitis (see Ch. CII, also Memorandum, 1943) Likewise, no clinical distinction is possible between postarsenical jaundice and infective hepatitis (Mitchell, 1943).

Pathological Changes

Changes and lesions are identical with those of infective hepatitis, see p 1165

History of Outbreaks

The disease first attracted attention in Great Britain in 1937 when 43 cases with 9 deaths occurred among a group of 123 children who received 2 batches of *antimeasles convalescent serum* (McNalty, 1938, and Memorandum, 1943). An outbreak at a mental institution under similar circumstances was reported by Propert (1938).

Postyellow fever vaccine jaundice.

In Britain, Findlay and MacCallum (1937–38) and Findlay (1940), first reported cases of jaundice contracted at intervals varying from 2 to 7 months after inoculation with tissue cultured yellow fever virus vaccine containing normal human

was reported from Brazil by Soper and Smith

ld War II when troops were mobilized and tlantic preparatory to service overseas, many thousands were inoculated against yellow fever in America, and certain batches of vaccine proved to be icterogenic. In the year 1942 an extensive outbreak was reported in the United States Army by Turner, Snavely, Grossman, and Buchanan (1944). A series of 10,284 cases, 31 of which were fatal, was investigated by Sawyer, Meyer, Eaton, Bauer, Putnam, and Schwentker (1944 *a*, *b*). The latter concluded that the cases were due to the introduction of an unknown icterus-producing filtrable virus in the blood of apparently normal blood donors whose serum was

reported the opposite effect. Conclusions have been drawn from the results of tests employing small numbers of human volunteers and are thus unsatisfactory.

Prophylactic value of gamma globulin.

If given during the incubation period of infective hepatitis it has been reported to modify the subsequent course of events, according to Stokes and Neefe (1945), Gellis *et al.* (1945 *b*), and Havens and Paul (1945).

Complement fixation reactions.

Attempts to elucidate specific reactions have been unsuccessful (Miles, 1946)

Attempts to Infect Animals

Pigs are said to have been infected with the virus of infective hepatitis in Denmark by Andersen and Tulinius (1938) but van Rooyen and Gordon (1942) failed to infect pigs.

Birds. Canaries are thought to be susceptible by Dresel, Meding, and Weineck (1943), and Herzberg (1943–4), but resistant according to Hoyle (1943).

Guinea-pigs. Verlinde *(1946) has claimed positive results.*

Rats. MacCallum and Miles (1946) produced lesions with blood and feces from cases of infective hepatitis in animals fed on a deficient diet.

Chimpanzees. Havens and Ward (1945) fed 6 of these animals with material known to contain infective hepatitis virus. The serum bilirubin, bromsulfthalein and cephalin flocculation tests were all negative and it was concluded that the animals were refractory to inoculation.

Monkeys Lasiopyga griseoviridis or *Cercopithecus aethiops* monkeys and Abyssinian baboons, *Papio hamadryas* were repeatedly inoculated with blood, urine, feces, and stomach washings by different routes but without success. Monkeys were also fed by stomach tube with several grams of desiccated serum from infective hepatitis cases mixed with powdered glass, but with no effect (van Rooyen and Gordon, 1942, van Rooyen and Kirk, 1946)

Mice, gerbilles (Gerbillus gerbillus) and *Gerbillus pyramidum, desert rats (Jaculus jaculus), pigeons,* and *kittens* were inoculated with blood from early and late cases of infective hepatitis. Liver tissue was inoculated for several blind passages, but with completely negative results throughout (van Rooyen and Gordon, 1942).

Chick embryos According to German workers a transmissible agent has been propagated in the chorio-allantoic membrane of chicken embryos (Siede and Meding, 1941, Dresel, Meding, and Weineck, 1943)

Elementary bodies were also said to be found in egg membranes and *in patients* (Essen and Lembke, 1944, Ruziczka, 1943) These claims have not been confirmed by Hoyle (1943) and others. Essen and Lembke (1944) claim to have found polyhedral-shaped elementary bodies, using the electron microscope.

Serum jaundice at a diabetic clinic.

Sixty-three cases with 4 deaths among elderly diabetics over 55 years of age were reported by Droller (1945) at a clinic in Sheffield, England. Here syringes were not sterilized by boiling but subjected to the worthless procedure of washing in sterile distilled water and storing in spirit.

Properties of Virus

Filtrability. The agent traverses the Seitz asbestos disk filter without difficulty (Findlay, MacCallum, and Murgatroyd, 1939, Sawyer *et al.*, 1944 *b*).

Heat It withstands heating at 56° C. for 30 minutes (Sawyer *et al*, 1944 *b*).

Cold. The virus can be preserved in carbon dioxide ice ... er *et al*, 1944 *b*) ... phenol and ether for ... morandum, 1943).

Inactivation by ultraviolet light.

According to Oliphant and Hollaender (1946), a strain of serum jaundice virus contained in pooled serum derived from an English blood bank was inactivated by ultraviolet light irradiation 16.0 ml. of icterogenic serum was placed in a quartz glass flask, which was suspended and rotated between eight 8-watt low pressure mercury vapor lamps, from which 80 per cent of the radiation was at 2,537 Å Samples of serum were withdrawn after 1, 6, and 30 minutes, respectively, and injected subcutaneously in 12 volunteers One of those receiving serum after irradiation for 6 minutes, developed jaundice 84 days later, but the remainder was unaffected throughout the period of observation for 161 days. Simultaneously, 12 controls were inoculated with untreated serum and of these 4 developed jaundice.

If satisfactory irradiation apparatus could be devised for effectively treating large volumes of serum, this work would acquire considerable importance, and the value of the method may be put to the practical test.

Attempts at cultivation and animal infection.

All efforts to infect chicken embryos with blood, filtered duodenal contents, ...

Human transmission experiments.

Following parenteral inoculation of serum jaundice virus the *incubation period* had been stated to be 72 to 132 days (Paul, Havens, Sabin, and Philip, 1945), 59 to 129 days (MacCallum and Bauer, 1944), 45 to 150 days (Spurling, Shone, and Vaughan, 1946), and 44 to 167 days (Grossman, Stewart, and Stokes, 1945) After yellow fever vaccine, the period has been estimated to be 60–150 days (Sawyer *et al.*, 1944 *b*) and 2 to 7 months by Findlay and MacCallum (1937, 1938)

Studies on postarsenotherapy jaundice have shown the incubation period to be 62 to 157 days (MacCallum, 1945) and 62 to 157 days (Howells and Kerr, 1946).

Distribution of Virus in Man

The virus of serum jaundice has been shown to be present in the peripheral blood of one volunteer 34 days after inoculation and 60 days before this man developed jaundice (Paul, Havens, Sabin, and Philip, 1945) The disease has also been transmitted by feeding with infected serum (MacCallum and Bauer, 1944), but when feces and nasopharyngeal washings from cases of postarsenical jaundice were fed, MacCallum (1945) failed to do so. Neefe, Stokes, and Reinhold (1945) fed 19 volunteers with 3 pools of feces from cases of serum jaundice gathered

incorporated in the manufacture of yellow fever vaccine. It was, therefore, recommended that serum-free yellow fever vaccine be prepared in future Other interesting points were that there were few, if any, secondary cases, and no evidence of the disease having been contracted from civilians or troops having infected civilians

(For jaundice following use of human *antimumps serum* administered to troops in England, see Beeson, Chesney, and McFarlan, 1944)

Jaundice following administration of human *anti-sandfly fever serum* has been reported from as far distant as the Black Sea Coast of Russia by Sergiev *et al* (1940).

Posttransfusion jaundice.

With the start of active warfare, many battle casualties and civilian air raid victims who received serum/plasma transfusions subsequently developed jaundice. Careful studies in Britain established many important facts. Thus, some pooled batches of serum and plasma were found to be more icterogenic than others and, of 1,054 patients transfused, 77 (7 3 per cent.) developed jaundice 45 to 150 days later (Spurling, Shone, and Vaughan, 1946, Bradley, 1946). The *pros* and *cons* of employing single donors for each recipient as opposed to use of pooled sera and plasma from multiple donors were also considered Loutit and Maunsell (1945) concluded that it would be safest to transfuse serum from individual to individual, but that small pools of serum and plasma gathered from not more than 10 persons be permitted The effect of dosage was also scrutinized and Loutit (1944) reported that 50 out of 54 patients could be infected with serum jaundice virus with doses of serum as small as 0 1 c.c. administered intradermally. MacCallum (1946) further stated that the size of the inoculum, within wide limits, had no effect upon the attack rate, incubation period, or severity of the illness.

Use of gamma globulin.

Disappointing results have been reported by Grossman, Stewart, and Stokes (1945) and Robinson *et al* (1946) Failure is not surprising because the incubation period of the disease is long and in all probability viremia is well established long before the onset of clinical jaundice (Paul and Havens, 1946).

Postarsenical jaundice.

The authors' own observations at certain venereal disease treatment centers, civilian and military alike, before and after the war, are in agreement with the comments of others, respecting the low standards of asepsis practiced at these institutions (Bigger, 1943, Beattie and Marshall, 1944) Even under wartime conditions of shortage of equipment, Salaman *et al* (1944) and Laird (1946) have shown that the disease is preventable by correct organization, discipline, education, and supervision of orderlies at clinics

The high incidence of jaundice among syphilitics treated with arsenic, prompted Peters *et al* (1945) to employ sulfur-coated amino acids in an effort to diminish the possible hepatotoxic action of arsenic, but without marked benefit In a memorandum (1945) it was concluded that late hepatitis after arsphenamine, gold, and other therapies is an expression of homologous serum jaundice communicated by traces of blood transferred on syringes and needles from patient to patient

Postpenicillin jaundice.

The continuance of jaundice at certain venereal disease treatment centers despite the advent of penicillin, strongly suggests that the major cause of jaundice past and present at these units has been faulty sterilization technique. (See Darmady and Hardwick, 1945, Howells and Kerr, 1946, Hughes, 1946, and Turner, 1946.)

from 7 days before appearance of jaundice to 18 days after it, but with negative results Findlay and Martin (1943) claim to have transmitted serum jaundice (employing icterogenic yellow fever vaccine) with nasopharyngeal washings.

Cross Immunity with Infective Hepatitis

The evidence is both conflicting and scanty. According to Oliphant (1944), individuals who had recovered from postyellow fever vaccine serum jaundice were resistant to reinfection with the homologous virus, as well as a strain of infective hepatitis virus, but Havens (1945 *b*) found that one attack of serum jaundice did not produce immunity against infective hepatitis, and Gauld (1946) observed that American troops who had previously suffered from serum jaundice, were two and a half times more susceptible than others to natural infective hepatitis when exposed to infection in Italy.

Experiments performed on small numbers of human volunteers, unless elaborately controlled, are prone to lead to statistically unsound deductions We lack much fundamental information, such as the relationship of the dosage of virus to the development of both varieties of infection. Some contend as little as a pin prick can convey serum jaundice. Others are uncertain. The authors know of a patient who was unaffected after transfusion of a pint of blood from a donor who developed jaundice the next day. In short, we possess no serological or immunological measure whereby the relative susceptibility or otherwise of an experimentally inoculated subject can be determined so as to permit interpretation of negative test with certainty. The relationship of these 2 viruses is subject to much conjecture We do not know whether they are different, closely related, or identical It has been tentatively suggested that clinical serum jaundice may represent the artificial production of infective hepatitis The latter possibility excites curiosity for if eventually the 2 are proved to be identical, then infective hepatitis virus may well be described as one possessing the unique property of extreme susceptibility to artificially induced variation such as by merely altering the natural avenue of infection in the normal host.
